CHEWABLE SORBITRATE®

(ISOSORBIDE DINITRATE) 5 mg or 10 mg

endable, prolonged protection during periods of emotional or physical exertion

ary Of Prescribing Information

tions: Based on review of this drug by The nal Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:
robably effective: The chewable dosage form of SORBITRATE is indicated for the treatment of anginal attacks and for prophylaxis in situations likely to provoke such attacks.
nal classification of the less than effective indications requires further investigation.

ndications: A history of sensitivity to the drug
ngs: Data supporting the use of nitrates during the acute phase of myocardial infarction are insufficient to establish safety.
tions: Tolerance and cross tolerance to other nitrates may occur.

Adverse Reactions. Headache which may be severe and persistent. Lowering the dose and using analgesics will help control the headaches which usually diminish or disappear as therapy is continued.

Adverse reactions seen occasionally: Cutaneous vasodilation with flushing; transient dizziness and weakness as well as other signs of cerebral ischemia associated with postural hypotension; individual marked sensitivity to the hypotensive effects of nitrates wherein severe responses can occur even with the usual therapeutic dose (alcohol may enhance this effect); drug rash and/or exfoliative dermatitis.

This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine and other agents.

Dosage and Administration: Individual Dose: To minimize hypotensive responses, which may occasionally be severe with chewable doses as low as 5 mg, the smallest effective dose should be employed. Chewable tablets are generally given in doses of 5 mg.

Dosage Schedule: Smallest effective dose necessary for the prevention and treatment of pain of an angina attack. CHEWABLE SORBITRATE (isosorbide dinitrate) may be taken for prompt relief of anginal pain three or four times daily. Although the onset and duration of effect of coronary nitrates may vary, following is the generally reported range of these values for CHEWABLE SORBITRATE.

Onset of Effect: Two to five minutes.
Duration of Effect: One to two hours.

"cardiac separation"...

Although over 80% of post ... patients can resume ... marital sexual activity ... of anginal pain often results in "cardiac separation" between patients and their families.

You can help minimize "cardiac separation" with a program of counseling and often with a prescription for Cardilate® (erythrityl tetranitrate).

Cardilate® increases exercise tolerance, helps patients return to more normal levels of activity—*including sexual activity.* Sublingually, Cardilate begins to work within 5 minutes, eliminating or reducing frequency and severity of anginal pain for up to 2 hours.

counsel & Cardilate®
(erythrityl tetranitrate)

CARDILATE® (ERYTHRITYL TETRANITRATE)

INDICATIONS Cardilate (Erythrityl Tetranitrate) ... ndicated for the prophylaxis and long term treatment of patient with frequent or recurrent anginal pain and ... associated with angina pectoris rather than for the treatment of the acute attack of angina ... onset is somewhat slower than that of nitroglycerin.

CONTRAINDICATIONS *Idiosyncrasy to this drug.*

WARNING Data supporting the use of nitrates du... the acute phase of myocardial infarction (the period during which clinical and laboratory findin... table) e... sufficient to establish safety.

PRECAUTIONS Intraocular pressure is increased ... required in administering to patients with glaucoma. Tolerance to this drug and cross toler... other ... tes and nitrates may occur.

ADVERSE REACTIONS Cutaneous vasodilation with ... g ... adache is common and may be severe and persistent. *Transient episodes of dizziness and weakness* ... the ... s of cerebral ischemia associated with ... ionally develop. *This drug can act* ... ological antagonist to norepinephrine ... marked sensitivity to the ... tion and collapse can occur even with the usual therapeutic dose. Alcohol may enhance this effect. Drug rash and/or exfoliative dermatitis may occasionally occur.

DOSAGE AND ADMINISTRATION

Oral Sublingual Tablets: Cardilate (Erythrityl Tetranitrate) may be administered either sublingually or orally. Therapy may be initiated with 10 mg prior to each anticipated physical or emotional stress and at bedtime for patients subject to nocturnal attacks. *The dose may be increased or decreased as needed.*

HOW SUPPLIED

CARDILATE (Erythrityl Tetranitrate) TABLETS (Scored) for ORAL or SUBLINGUAL USE 5 mg Bottle of 100; 10 mg Bottles of 100 and 1000; 15 mg Bottle of 100

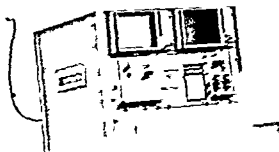
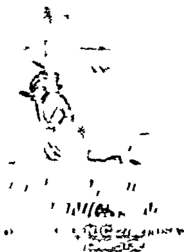
DOPSCAN®

The noninvasive, ultrasonic, stroke screening system to evaluate the carotid bifurcations

Color spectrum analyzer is available.



DOPSCAN® is a Doppler arterial scanning system for early detection of potential stroke conditions



It provides a noninvasive evaluation of the carotid bifurcations and other peripheral arteries to indicate the location and severity of arterial insufficiency and plaquing It is a valuable supplement to X-ray angiography

DOPSCAN® provides a set of permanent exam records (1) Magnetic tape recordings of the Doppler flow sounds with the flow information in aural form along with the operator's commentary (2) Strip chart recordings showing pulsatile velocity waveforms and flow direction, and (3) Mapped images of the carotid bifurcations

An optional Sonascope™ Spectrum Analyzer designed specifically for the DOPSCAN® provides a color and real time display of the Doppler flow signals It separates arterial and venous flows and displays both simultaneously

The North American Society of Pacing and Electrophysiology Young Investigators' Award For 1981

1st prize $1000 00 2nd prize $500 00
Honorable Mention $250 00

The North American Society of Pacing and Electrophysiology (NASPE) invites submission of manuscripts for competitive review and eventual presentation of the 1st and 2nd prize winning papers at its 2nd Annual Scientific Symposium on March 14th 1981 in San Francisco California The goal of this award is to encourage and give recognition to able young investigators for original investigation or basic research in the area of Cardiac Pacing and/or Cardiac Electrophysiology

ELIGIBILITY

Any physician or scientist who is presently involved in an active fellowship or residency program or who has been involved within the past three years is eligible to participate This includes medical students and PhD candidates Applicants must reside within or have received their academic training within the geographic boundaries of North America *

DEADLINE FOR SUBMISSION OF MANUSCRIPTS DECEMBER 15 1980

RULES

1 The investigation upon which the manuscript is based must be an original piece of investigation performed predominantly by the first author
2 The applicant must attest that the investigation has not previously been reported or published elsewhere and that if chosen by the judges as a prize winning entry will not be presented or published prior to March 14 1981
3 Award winning manuscripts will be published in PACE The Journal of Pacing and Electrophysiology
4 Abstracts of non award winning manuscripts deemed by the judges to be of high reader interest will also be published in PACE
5 Authors of award winning manuscripts are expected to attend the 2nd Annual Scientific Program of NASPE both for presentation of a 15 minute summary of their manuscript (1st and 2nd prize only) and receipt of awards

EDITORS! REVIEWERS! AUTHORS!

For you a new book that contains virtually everything you want to know about

THE SCIENTIFIC JOURNAL EDITORIAL POLICIES AND PRACTICES

Guidelines for Editors, Reviewers, and Authors

In 1665 the first scholarly journal was published in France Since that time there has been no one source of editorial guidelines for journal editors This new book now provides you with such a source

YOU DECIDE YOUR OWN APPROACH!

Presenting the advantages and disadvantages of each specific decision eminent editors offer you various recommendations discussions and opinions concerning the problems you may encounter

Because we are aware that there is no right policy on most editorial matters we have tried not to prescribe rules but have instead explored various facets of the problems that confront the editor in his daily work

The book is divided into two general sections editorial policies which usually require major decisions and editorial practices which involve minor decisions often about format or mechanical style You ll find essays exploring the manuscript reviewing system special types of manuscripts (abstracts transactions solicited manuscripts book reviews) You ll value chapters which cover information for authors copyright, errata references cited copy editing journal cover etc

From the purpose of scientific journals to binding practices this new book contains virtually everything you want to know as editor reviewer or author See for yourself!

If you think the EK-8 is a fast recorder, see how it saves mounting time!

You know the Burdick EK 8 ..s a complete 12 lead ECG ..tomatically ... in less than ..3 seconds

That s impressive in a ..ngle channel cardiograph

But there s another important ..art to the EK 8 story

The EK 8 was designed to ..ve physician and staff time And ..ile it makes good sense to save ..e recording the ECG think of ..e additional time saving benefits ..hen you can mount and fil.. the ..CG in less time than it take.. ..cord the 12 lead tracing

That s why the EK 8 fast mounting system is important to you The answer is in our unique card and folder format mounts When the ECG is recorded the *technician takes the complete* tracing with each lead already clearly marked and quickly positions it on the pressure sensitive card or folder format mount No die cutting No pasting or taping It s *ready for filing* It can take less than a minute to record *and* mount the ECG

The Burdick mounting system Because the ECG isn t complete until the paperwork s done

Find out how the EK 8 can increase your ECG productivity from start to finish Call or write **The Burdick Corporation** ***Milton Wisconsin 53563***

lew 4th Edition! **THE HUMAN HEART**
, Guide to Heart Disease By Brendan
hibbs MD F.A.C.P., F.A.C.C. with 5
ontributors A simple and practical guide
overing many aspects of heart disease,
his new 4th edition succinctly explains the
natomy,physiology and common diseases
f the heart. Information on drugs
mergency resuscitation,
atheterization and heart surgery
s well illustrated and provides an
xcellent reference for you - and
our staff August, 1979 288 pp
80 illus Price $13 95

lew 4th Edition! **COMPREHENSIVE**
CARDIAC CARE. A Text for Nurses
Physicians and Other Health
Practitioners By Kathleen G
Andreoli, R.N B.S.N. M.S.N
Virginia Hunn Fowkes, R.N B.S.N
Douglas P Zipes M.D and Andrew
J Wallace M.D This new edition
will give you the information on
all aspects of cardiac care -
anatomy and physiology- coronary
artery disease assessment of patients
complications electrocardiography- and
pacemakers New material covers risk factors
in coronary artery disease- interview physical
examination, and common laboratory
for patients with coronary
artery disease- and current
pacemaker therapy March, 1979
406 pp 699 illus. Price $12.50

CLINICAL ECHOCARDIOGRAPHY
By Navin C. Nanda M.D and
Raymond Gramiak, M.D This clinically-
oriented text is an excellent guide to
applying echocardiographic techniques in patient
evaluation. The authors first describe pertinent
physics, equipment, and recording methods and
review cardiac anatomy electrocardiography
phonocardiography and hemodynamics in relation to the performance and
interpretation of echocardiograms Section two discusses echo exam
techniques and skill acquisition. Throughout, emphasis is on technical
proficiency and interpretive expertise. 1978 468 pp 666 illus
Price $41.50

4th Edition **BLADES' SURGICAL DISEASES OF THE CHEST**
Edited by Donald Brian Effler M.D with 33 contributors. The 4th
edition of this widely respected volume presents the latest
developments in thoracic and cardiovascular surgery Throughout,
you'll share the viewpoints and experience of more than 30 contributors
— many new to this revision — all recognized authorities in their
respective fields. A particularly noteworthy chapter by Kazi Mobin-Uddin
discusses the surgical aspects of thromboembolism. 1978 856 pp
939 illus. Price, $65 00

New 2nd Edition! **MYOCARDIAL INFARCTION.**
Electrocardiographic Differential Diagnosis By Ary Louis
Goldberger M.D The 2nd edition of this unique reference extensively
details all major conditions that cause ECG changes which mimic
infarction patterns. It offers guidelines to help you differentiate
between actual and pseudo-infarct patterns and aids in diagnosis.
Three new chapters highlight this edition.
All deal with various aspects of
ST-depression, ischemic causes normal
variant and non-ischemic causes and false
positive exercise tests April, 1979
296 pp 336 illus Price, $27.50

New 2nd Edition! **CARDIOVASCULAR NUCLEAR MEDICINE.** Edited by H.
William Strauss M.D and Bertram Pitt,
M.D with 41 contributors An authoritative
overview of cardiovascular nuclear
medicine this revised and updated 2nd
edition presents not only the latest
techniques but also historical and
background information on the state of the
art. Of particular importance are two new
chapters Computer methods in nuclear
cardiology by David Lieberman and
Emission computed tomography of the
myocardium by John Keyes.
September 1979 442 pp
693 illus plus 4 in
full color Price $47.50

A New Book! **ISCHEMIC HEART DISEASE.** By I.K
Shkhvatsabaya Translated
by V.N. Bobrov and G S Vats
Don't miss this important
contribution to international medical
literature from Russia It discusses
some problems of ischemic heart disease
on the basis of experimental epidemiological and clinical
investigations conducted at The Myasnikov Institute of
Cardiology in the U S S R. Chapters detail the epidemiology
pathogenesis diagnostics management, rehabilitation and prevention
of ischemic heart disease June 1979 423 pp 123 illus Price $37.50

A New Book! **THE CARDIAC CYCLE.** By M.I.M. Noble Ph D M.D
F.R.C.S Based on the work of some of the world's leading investigators,
this new book reviews the latest ideas on the events in the cardiac cycle
from the pacemaker to the peripheral pulse Some of the theories
introduced by the authors are experimental and have yet to be proven
by critical test. Major sections of the book include the electrical cardiac
cycle the calcium cardiac cycle mechanism of contraction, and control
of the cardiac contractile performance. December 1979 Approx. 224
pp 90 illus About $38 75

*Indications Based on a review of th s dr g by the National Academy of Sciences—National Research Council and/or other inf rmation FDA has class fied th ind cations as follows
Possibly effective When taken by the oral route Isordil is indicated for th relief of a gina pectoris (pain of coronary artery disease) It is not intended to abort the acute anginal episode but is widely regarded as use ul in the pro hylactic treatment of angina pectoris
Final cla sif cation of th less than-effective i dications requires further investigation.

Contraindication Idiosyncrasy to this drug

Warnings Data s pporting the use of nitrites and nitrates during the early days of th acut phase of myocardial infarction (the period during which cl n ical and laboratory findi gs are unstabl) are in ufficient to establish safe y

Precautions Tolerance to this drug and cross tolerance to other nitrites and nitrates may occur

Adverse Reactions Cutaneous vasod lation with flushing Heada he is com mon and may be severe and persistent. Trans ent episod s of dizziness and weakness as well as other signs of cerebral ischemia associated with postural hypoten ion may occas onally develop This drug can act as a phys ol gical a tagon t to norepinephrine acetylcholine histamine and many other agents An occasional individual exhibits marked sensitivity to the hypotensive effects of nitrite and severe responses (nausea vom g w akness rest essn ss pallor perspiration and collapse) can occur even with the us al therapeutic dose Alcohol may enhance this effect. Drug rash and/or exfoliative dermat tis may occasiona ly occur

Dosage and Administration: Isord l (Isosorbid Dinitrate) Oral Titradose Tabl ts are administered orally The dosage range is 5 mg to 30 mg q i d with the usual dosage bei g 10 mg to 20 mg q i d

Consult direction circular before prescribing.

for "cardiac separation"...

Although over 80% of post coronary patients can resume normal marital sexual activity fear of anginal pain often results in "cardiac separation" between patients and their families

You can help minimize "cardiac separation" with a program of counseling and often with a prescription for Cardilate (erythrityl tetranitrate)

Cardilate increases exercise tolerance helps patients return to more normal levels of activity—including sexual activity

Sublingually Cardilate begins to work within 5 minutes eliminating or reducing frequency and severity of anginal pain for up to 2 hours

VARIAN V-3400

Setting New Standards In Sector Scanning

FEATURES

Digital Scan Processor (DSP)

The Varian DSP uses a powerful microprocessor system to fully utilize digital technology for processing the ultrasound image

Phased Array Design

Varian pioneered the success of phased array transducer technology which requires no moving parts and yields significant performance advantages

Varian Ultrasound

From pioneer to premier manufacturer Varian is a major high-technology corporation consistently leading the way in product technology, responsive field service and customer education

BENEFITS

Excellent Imaging Quality

The V 3400 produces clear low noise high sensitivity, diagnostic quality images from all major anatomic windows

Dependable Performance

Inherent reliability solid state electronics and phased array design combine with Varian s experience and extensive customer support to ass dependable clinical performance

Advanced Clinical Capability

Fast accurate examinations recording and quantitation are enhanced by the V-3400 advanced clinical features such as variable persistence pre and post processing simultaneous M mode and the light pen measurement system

One disposable dome stands out from every other in sight Why? Probably because Bell & Howell s DISPOSADOME® excells in so many ways

Some say they like the convenience It s so fast and easy! (They refer to the individual snap open sterile package and quick installation — you don t have to use a fluid between the membrane and the transducer diaphragm — and of course the disposable feature)

Some quote the economy factor (Yes, considering the time and labor costs for cleaning and sterilizing other types — plus the possibility of transducer damage — that s certainly true)

Others agree to these advantages but additionally cite the ready availability of either Linden or Luer fittings (And we might add you can switch transducers or domes without disturbing the fluid path)

Whatever your reasons for helping to make DISPOSADOME famous you also have the assurance of the Bell & Howell name and experience And that s really the best reason of all

(DISPOSADOME is designed exclusively for use with Bell & Howell physiological pressure transducers.)

Editorial

Thomas Young, M D (1773-1829)

The mechanical motions which take place in an animal body are regulated by the same general laws as the motions of inanimate bodies
Thomas Young 1808

J D Laird
Leiden The Netherlands

Thomas Young physician natural philosopher and philologist possessed beyond doubt one of the truly greatest minds at work as the eighteenth century drew to a close His contributions to our understanding of both ourselves and the world around us were legion and although this by itself would be reason enough for a few moments reflection and indeed homage in 1980 I feel compelled to seek further rationalization for intruding on the busy schedule of the cardiovascular specialist

A Frenchman is said to have remarked when considering the contribution of William Harvey that the facts were all there and indeed were so simple that any schoolboy would have been able to put them together It was nonetheless Harvey who did so And where is that clever schoolboy at this point of time in the evolution of our understanding of cardiovascular disease and particularly of ischemic heart disease? This multifactorial disease seems to present an intellectual challenge *just* beyond the grasp of the established investigators of today Was it really so much *easier in the good old days when the body of* knowledge was so much smaller that one person could develop a commanding knowledge over a broad area of science? I doubt it

We are not the first generation forced to grapple with concepts beyond both our reach and understanding so perhaps we can profit from considering the accomplishments and indeed the failures of one of the most adroit interdisciplinary intellects of all time Books have been written (see bibliography) about Thomas Young's many and varied accomplishments and in the short space of this article I wish to call attention to some of his lesser contributions of particular interest to the cardiovascular specialist For it is the curious burden to be borne by the greats that these lesser contributions often fail to receive the attention they deserve Achievements which for a lesser mortal might constitute success beyond imagination are doomed to be forgotten so overshadowed are they by other pinnacles of intellectual brilliance And so it was with the lesser contributions of Thomas Young As great as they were they paled when seen in the light of his brilliant discovery of the principle of wave interference of light his unravelling of some of the mysteries of physiological optics or his discovery of the clue to the decipherment of the Rosetta Stone eventually leading the western world to the key for unlocking the cultural treasures of ancient Egypt

Was it his genetic material or the environment of his youth which fell a goodly number of standard deviations away from the mean of his

fellow men? Probably both but in what measure each contributed to his genius is unknown and every proposition is pure conjecture

The 1 th of June 1773 does not catch England at its best As personal intolerance was on the wane at home turbulence and conflagration become more and more characteristic of foreign affairs In the western counties of England little of this could be felt and such was the isolation that the little village of Milverton eight miles from [illegible] counties of Somerset knew little more of the world than the decline of the wool industry [illegible] the backbone of the local agri[illegible] Young s father Thomas Young [illegible] a successful mercer and [illegible] diversified into banking As [illegible] of Milverton so enervated [illegible] tual and cultural life of Thom[illegible] more important than the con[illegible] tability of his parents were their [illegible] tions They were members of the Society of Friends or Quakers Although tolerance was on the rise again this was not an easy thing to be in the England of 1773 The scars both literal and cultural on the family circle plus the dogma of this faith itself fostered an intense adherence to the serious strictures of the sect as well as stimulating a nearly obsessive self reliance and personal responsibility The Quakers belief in an inner light and the obligation of each individual to continually search in and through himself for the truth formed a driving force in Thomas Young s early education which is difficult to imagine today

A compilation of his early education is enough to cause the present day student of medicine or physics including this author to stop be silent and reflect for a few moments Upon reaching the age of two he had learned to read with in his own words considerable fluency and before reaching the grand age of four had read the bible twice through For unclear reasons he spent the better part of his first seven years with his maternal grandfather Robert Davis in Minehead One reason may simply have been practical he was the eldest of ten children or it may have been the early recognition that this genius required special care In any event he soon became a favorite of Mr Davis Young Thomas apparently took to heart the oft repeated admonishment of his grandfather that A little learning is a dangerous thing Drink deep or taste not the Pierian spring After an abortive year and a half at a miserable boarding school he spent six months of his eighth year at home In these months he spent a good deal of time at the home of his neighbour a Mr Kingdon a practical man of great ingenuity who had raised himself from tailor to land surveyor This encounter is significant for its demonstration of an early interest in science There he found many books relating to science and particularly a Dictionary of Arts and Sciences in three volumes folio which I began to read with the most intense interest and delight at this house I also found several mathematical and philosophical instruments The following spring when nearly nine years old he was sent off to a boarding school in Compton Dorset The Compton school s contribution to the nurturing of the phaenomenon Young appears to consist of equal parts classical education with emphasis on Greek Latin French Italian and Hebrew and the informal education provided by Mr Josiah

Jeffrey the school s usher and apparently also its entrepreneur It seems he had a lively private trade going with the young scholars in paper copper plates copy books and colours Jeffrey lent Young *Martin s Lectures on Natural Philosophy* the optical part of which especially caught the boy s fancy The pre teen Young under the tutelage of Jeffrey further broadened his skills by learning the use of a lathe the making of a telescope grinding and preparation of colours and the binding of books Already he apparently demonstrated a nearly obsessive and jealous guarding of his precious time which as his biographer Wood demonstrates he quite literally carried to his deathbed In his own words I was in the habit of rising an hour sooner than my school fellows in summer and of going to bed an hour or two later in winter for the purpose of mastering my lession for the day my school business was thus soon finished

None of the writings concerning Thomas Young give any really clear indication of the process by which his career choice was made Apparently it was just as random a process as with more mortal souls As fate would have it his uncle was the very successful rich and influential physician Richard Brockelsby (1722 1797) Before leaving school at the age of 13 Thomas had a brief encounter with Morris Birkbeck from which he imbibed a wish to study Botany This wish apparently took a turn later towards Medicine though not before he acquired a lathe of his own and had made himself a microscope Via a complex net of family and Quaker friends arrangements were made for his further education At 14 he was sent off to Youngsbury to become the study companion of Hudson Gurney (1777 1864) who later became a rather well known antiquary writer and member of parliament Both boys labored under their tutor a well respected and some say brilliant John Hodgkin However there seems to be in the case of Young some uncertainty with respect to who was doing the tutoring Method notwithstanding Young s knowledge of languages flourished in this period and a copybook containing extracts of the Bible in English French Italian Greek Hebrew Chaldee Syriac Samaritan Arabic Persian Turkish and Aethiopic are admired by his biographer Peacock for of all things their beautiful penmanship

This period of intense scholarship and accomplishment was suddenly interrupted at the age of 16 by a serious respiratory illness verging on consumption With careful nursing he eventually recovered though it was apparently serious enough to elicit a letter from his physician uncle Richard Brockelsby admonishing him to take better care of himself and expressing the opinion that eating a little fish twice or thrice a week would do no harm but you must make the trial cautiously In the same letter his uncle takes Thomas to task for his prudery about abstaining from the use of sugar on account of the Negro Trade In those times this was a form of symbolic protest fairly common among Quakers and other activists

By the time he left Youngsbury at the age of 19 not only was his classical education up to a level which allowed him to discuss as an equal with the scholars of his time but moreover he was widely read in science having ploughed through the works of Newton Linnaeus Lavoisier and Black and Boerhaave

He spent little time at home during this period and four months each winter were spent in the London home of the Barclays in Red Lion Square This seemingly insignificant fact is nonetheless noteworthy for it gives us a hint of the process by which Young s eventual career choice was made It was a chance for Young to sample the civilized life of cultured London to attend concerts lectures to move in literary circles to polish his social graces and to try out his intellect against worthy competition Moreover it was in the periods of his London residence that his remarkable abilities came to the attention of his uncle Brockelsby who it would appear was largely responsible for steering Thomas Young in the direction of Medicine

As an interesting aside the practice of medicine was in those days still referred to as the practice of Physic whereas what we now call physics was termed Natural Philosophy the quite arbitrary and artificial distinction between the two fields being hidden by changes of language Both Physics and Physician stem from the Greek φυσικοσ meaning Natural [1]

Young s approach to problems was strongly influenced by firm belief in several guiding principles As I have already mentioned he jealously guarded his life against the dangers of wasting time Hudson Gurney his study companion wrote of Young that at no period of his life

was he particularly fond of repeating experiments or even of very frequently attempting to originate new ones considering that however necessary to the advancement of science they demanded a great sacrifice of time, and that when the fact was once established that time was better employed in considering the purposes to which it might be applied or the principles which it might tend to elucidate Moreover he was personally persuaded of both the effectiveness and advantage of self study and at 19 wrote to his brother, Robert

Although I have readily fallen in with the idea of assisting you in your learning yet it is in reality very little that a person who is seriously and industriously disposed to improve may not obtain from books with more advantage than from a living instructor Something is wanting for the direction of application in the right path but it must be the strength of the traveller and not of the guide that must conquer the difficulties of the journey Masters and mistresses are very necessary to compensate for want of inclination and exertion but whoever would arrive at excellence must be self taught

As Peacock asks What then were the primary causes of the extraordinary success of an education conducted for so many years with so little communication with other minds with so little assistance from extrinsic sources? The principal of these must be referred to the peculiar constitution of his own mind to his great industry, to the conviction which he always felt that what one man had accomplished another might accomplish also

Young himself in a letter to his uncle in 1792 quotes some lines of a poem by Barnard as expressing his view Thou say st not only skill is gained But genius too may be obtained by studious imitation Peacock continues He had little faith in any peculiar gifts of genius believing the original difference between human intellects to be much less considerable than it was generally supposed to be His temper also in early youth was singularly unruffled and tranquil he had no boyish tastes or amusements he was educed by no dreams of the imagination from the assiduous cultivation of understanding This briefly was the young man of 19 who set off to London to study medicine in 1792

Young followed lectures in the Hunterian School of Anatomy founded by William Hunter and set forth by Bailie and Cruikshank It is difficult to visualize today but in those days the ' West End was still very nearly just that and the anatomy lectures were held in a small building on Great Windmill Street which has long since been incorporated into the Lyric Theatre on Shaftsbury Avenue It would appear that the interest in Anatomy in the Soho district of London has deeper cultural roots than might at first be evident

Young was very quick to distinguish himself demonstrating his almost uncanny ability to reach into his already vast store of knowledge (in this case, optics) and apply it to his current area of study While dissecting the eye of a recently slaughtered ox he became intrigued by the mechanism of accommodation His investigations led him to the conclusion among other things that variation of the focal length of the lens itself was responsible Young communicated his finding in a paper read to the Royal Society in May 1793 This paper by a second year student caused something of a stir embroiling him in a not altogether pleasant debate concerning both the correctness and the originality of his work While others debated the latter Young himself questioned the former Both were eventually resolved and in the summer of 1794 Young was elected to Fellowship of the Royal Society on the strength of this work

Having begun with something of a splash Young on whose advice is not clear journeyed on horseback to Edinburgh to continue his studies Armed with letters of introduction and a curiosity as broad as his knowledge he made quite a tour of it In his travels through Derbyshire and Yorkshire he examined with his accustomed activity and intelligence the collections of art or natural history mines mineral springs manufactures or other curiosities Having spent some time visiting Erasmus Darwin the grandfather of the great naturalist he left with yet another letter of introduction to an Edinburgh friend stating He unites the scholar with the philosopher and the cultivation of modern arts with the simplicity of ancient manners

The medical school of Edinburgh then so highly regarded by most did not escape without the criticism of its new student While he later concludes that Edinburgh had much to recommend it to the student of medicine he was able to share his attention between his study and taking flute lessons learning to dance to enjoy the

theater and other naughty things he had missed in his strict upbringing I hasten to add that the list of activities makes very light reading by current standards

Having taught himself German he set off to continue his studies in Gottingen and so it was that on the 10th October he left Yarmouth on the packet boat Although the university enjoyed a very high reputation at that time Young was not sad to leave with his doctorate in July 1796 He had already become accustomed to being treated as an equal by the respected top and found the formality of German university life not his cup of tea

It would seem that professional bureaucracy is not a new invention for on his return to England Young ready to practice medicine was tripped up by the fine print of regulations Although a bit oversimplified the practical consequence of the rules was that in order to become a fellow of the College of Physicians a degree from either Oxford or Cambridge was required Thus rather reluctantly and largely as an expedient he entered Emanuel College Cambridge and shall barely keep the term for two years which will be more convenient to me than

His lack of commitment to his formal study in Cambridge did give him the spare time for an active social life as well as the opportunity to do some experimental work on the propagation and character of both sound and light waves These ideas first occurred to Young while he was working on his dissertation in Gottingen and were written up in the summer of 1799 after his completion of the required six terms of residence in Cambridge Thus in the last year of the 18th century Thomas Young set off on his dual career as physicist and physician

It is hard to believe that just one man was responsible for his output during that first decade of the 19th century

In 1801 he was appointed Professor of Natural Philosophy at the recently founded Royal Institution and began at once preparing a Course of Lectures on Natural Philosophy and the Mechanical Arts Young set as his goal a complete review of the state of knowledge in Physics up to that point and attempted to cast it all in language suitable for a mixed audience

The enormous diversity of his mind is nowhere more evident than in these lectures It is easy to presume that in those days the body of knowledge was so circumscribed that all that was known could be comprehended by one albeit clever man Those were the days when a physician could do fundamental and significant research in physics—the days before the information explosion before the Xerox machine It was therefore something of a shock to note Thomas Young s words in the Preface to the published lecture notes which appeared in 1807 I had in some measure pledged myself to make a catalogue of the best works already published on the several subjects with reference to such passages as appeared to be most important Hence arose a catalogue of references respecting which it is sufficient to say that the labour of arranging about twenty thousand articles in a systematic form was by no means less considerable than that of collecting them The transactions of scientific societies and the best and latest periodical publications which have so much multiplied the number of the sources of information constituted no small part of the collection which was thus to be reduced into one body of science

Notwithstanding the comprehensive nature of the lectures or the original ideas they contained the series of 31 lectures the first year expanded to 60 the second was not a great success It appears that in striving to achieve a balance between rigor and completeness on the one hand and comprehension by a mixed audience on the other he badly misjudged the general public This is in contrast to the far more successful but less original lectures of Davy on chemistry given at about the same time

Young s lectures have achieved a form of immortality granted only a very few It is in the thirteenth lecture that he introduces the concept of a modulus of elasticity with which his name is still associated It must be conceded that even a well taught mechanical engineer would have difficulty reçognizing Young s Modulus of Elasticity as defined in that lecture The modulus of elasticity of any substance is a column of the same substance capable of producing a pressure on its base which is to the weight causing a certain degree of compression as the length of the substance to the diminution of its length In fairness to Young it must be realized that he was wrestling with the concepts of what we now call stress and strain without the benefit of the contributions of calculus or the great French mathematician Cauchy who sorted it all out in his 1822

paper for the French Academy of Sciences The definition of Young s modulus in terms of the slope of the stress strain curve was actually proposed by Navier in 1826

In the same lecture Young applies the concept of a stress without naming it to muscle mechanics noting that it is obvious that in muscles of the same kind the strength must be as the number of fibres or as the extent of the surface which *would be formed by cutting the muscle* across

In 1802 Young delivered the Bakerian Lecture to the Royal Society On the Theory of Light and Colours in which he put foreward what is in slightly modified form known today as the Young Helmholtz theory of color vision

Perhaps his most important contribution was to the theory of light itself which he developed in a series of four papers published during the first four years of the 19th century Although only 30 at the time these papers represented the culmination of a train of thinking reaching back into his youth As a boy he was fascinated by optics His researches for his dissertation in Gottengen were devoted to an attempt to derive a system or alphabet for describing all the sounds which could be formed by the human voice thus forming a basis for an alphabet for all languages Via his studies on the formation and propagation of sound he began to see analogies with the propagation of light Building on this base the concepts were expanded during the ample spare time available to him in his Cambridge days and were presented in his 1800 Philosophical Transactions paper entitled Outlines of Experiments and Enquiries Respecting Sound and Light Unfortunately young Thomas in this paper *needlessly* took a rather mean swipe at the eminent mathematician and astronomer Dr Smith and one may speculate that in view of later events he would have wished for more self control

His subsequent three major papers set out with uncommon clarity the basis for the wave theory of light including an unambiguous statement of the principle of superposition of waves leading to *interference patterns In a minor* but nonetheless intriguing paper published in 1802 in the Royal Institution Journal under the title Harmonic Sliders *he gives details of a simple machine* for visually demonstrating the effect of superposition of sine waves coming very close to *enunciating* what we now call Fourier synthesis In 1807 with *the publication of his* Course of Lectures on Natural Philosophy Young essentially rounded off his momentous contribution to the subject

One would expect that such a profound series of papers on a subject which had been festering unresolved since Newton s efforts would have shaken the world of science causing great excitement Nothing could be further from the truth Young was quite simply ignored and the vast majority of active scientists apparently failed to grasp the significance of his work Even more painful was the vehement attack on his work and his imprudent remarks on Smith by Robinson and subsequently by Brougham The exchanges were increasingly nasty and founded more on personal dislike than on scientific merit They achieved their end to inflict pain and to cast doubt upon Young s reputation as a physicist Even more *difficult* for him to accept was the prejudicial effect on his medical practice which already was suffering from a certain dilution of attention In gross oversimplification it was a dark period for Young personally and for the development of the theory of light up until Fresnel s original and powerful support given in 1815 1816 As Wood states in his extensive account of Young s contributions Fresnel must *be reckoned as sharing with Young the honour of* establishing the wave theory on a broad and sound basis In Young s own words The theory of light and colours though it did not occupy a large portion of my time I conceived to be of more importance than all that I have ever done or ever shall do besides

And what did Thomas Young do with all his spare time during the development of his ideas *on light*? Among other things he made a contribution which is to this day of significance to the practicing cardiologist The law of LaPlace as we know it today relates the pressure difference across a curved surface to the tensions which must obtain at the surface itself *It constitutes an* extremely powerful concept for relating the forces which must be developed by the myocardium to raise the required pressures in the ventricle Not only is hypertension an excessive load on heart muscle but less obvious and equally true a big heart is a bad heart Now it so happened that LaPlace read his paper on the subject in 1805 and published it in 1806 But on the 24th of December 1804 Young presented his Essay on the Cohesion of Fluids to be published in the *Philosophi*

cal Transactions of 1805 The rival claims of priority by these two giants took some time to be resolved and although there was controversy it was pale by comparison with the debate over the theory of light In a feeble attempt to redress the matter I personally now refer to the relationship as the Young LaPlace Law The supplement to the fourth edition of the Enclycopaedia Brittanica contains a more fully developed article by Young in which he not only presents the Young LaPlace Law but also makes the very first estimate of the diameter of a molecule getting within a factor of 100 correct which was pretty good going for the beginning of the 19th century

Another contribution which may interest the cardiologist was his invention of the kymograph which in the hands of physiologists has revealed most of what we know of the processes of life A drawing of an elementary form of this device is contained in the plates accompanying the published version of his lectures on natural philosophy

In the *Philosophical Transactions of 1809* he published the text of his Croonian Lecture before the Royal Society On the Function of the Heart and Arteries This together with his paper entitled Hydraulic investigations subservenient to an intended Croonian Lecture on the motion of blood which appeared in the year before constitute a milestone in cardiovascular mechanics In the 1808 paper Young gives an analysis of the pressure flow relations in tubes and was well ahead of his time in describing the scaling laws of such a flow The relative importance of the square law vs the linear Poiseuille like term are discussed as a function of dimensions velocity viscosity etc In fact the essence of scaling with Reynolds number is clearly enunciated roughly 40 years before Osborne Reynolds carried out his crucial experiments

In the same papers Young analyzes for the first time the nature of pulsating flow in distensible vessels He derives an expression for the speed of propagation of waves in arteries and gives the method for computing it although once again without calculus and the modern definition of Young s modulus this formula is couched in rather obscure and impenetrable language The modern form of this expression is generally referred to as the Moens Korteweg equation and was presented roughly 70 years later In a clear and straightforward line of reasoning Young applies these concepts to deductions concerning the nature of the pulse in various pathological states and with a view to resolving the debate over whether the muscular coat of arteries play a role of significance in blood flow He concludes against the operation of the muscular powers of the arteries in the ordinary circulation

In 1803 after two years of lecturing on natural philosophy embroiled in controversy and concerned with the progress of his medical practice he resigned his professorship at the Royal Institution in the hope of devoting a greater part of his attention to medicine

In 1811 Young joined the staff of St Georges Hospital and remained happily associated with the hospital until his death 18 years later He set out to do for the practice of Physic what he already had done for physics to set down in a form nearly similar relating to every department of medical knowledge it will be comparatively more concise than these lectures [on natural philosophy] in proportion to what has been said and written respecting physic but I hope much more complete with regard to all that is known with certainty and can be applied with utility The results of these labors was *An introduction to Medical Literature including a system of Practical Nosology intended as a guide to students and an assistant to practitioners* published in 1813

In this work the first chapter contains some interesting glimpses of his views on the practice of medicine and on the most appropriate education illustrating his lack of comprehension of the limitations of his less well endowed fellowmen I shudder to think what would be the reaction of our students today were we to put into practice his belief that his own lectures on natural philosophy probably contain as much of natural philosophy as is absolutely *necessary for* a medical student Once again he was not a popular lecturer badly overestimating his audience

As near as can be determined it would seem that Young was a competent physician but never succeeded in attaining any real measure of popularity or success Peacock blames this on Young s approach to patients gentle and gentlemanly but not genial Both Wood and Hervel support the view of Young s colleague Dr Brodie who attributes his lack of success to the lack of constant attention to nurturing his practice due

to the demands of his other interests His practice slowly declined as his interests turned to Egyptology to which he made major contributions and because of his tasks of Secretary of the Board of Longitude and Superintendent of the *Nautical Almanac*

Sadly very little seems to be known of his private life In the summer of 1804 he was married to Eliza Maxwell and this relationship would appear to have been quite simply a happy and affectionate one In 1821 they travelled together to the continent and in the course of this rather grand tour he met with LaPlace In 1827 Thomas Young was elected as Foreign Member of the Academy of Science at Paris succeeding to the chair left by the death of Volta earlier that year

Early in 1829 Young began to suffer from repeated attacks of asthma and general weakness He managed to muster the strength to continue attendance at the Council meetings of the Royal Society his last being the 26th of March 1829 In bed he struggled with pencil for he could no longer hold a pen fast to complete his *Rudiments of an Egyptian Dictionary*

Thomas Young died on the 10th of May 1829 at the age of 56

In the seventh volume of the case notes of Dr Brodie one finds a page Examination of the Body of the late Thomas Young M D For Sec Royal Soc May 11, 1829 The cavities of the heart but especially those of the left ventricle were of unusual thickness (The latter might be of double the usual thickness) The sigmoid valves of the aorta were very slightly ossified in spots The aorta from its origin to its bifurcation was ossified to a very great extent so as to form thoughout the greater part of its extent a hard unyielding tube No man alive then and only a few after him would have understood as well as Thomas Young the significance of these findings

Throughout his life there is a sad strain of unfulfillment and frustration so undeserved since we are all so much richer for his contributions In 1813 Young wrote I think if I happen to live to be about 200 I shall begin to reap some little credit and emolument from the labours of my youth—but at 100 I shall be still a boy in public opinion

I would like to express my appreciation to the staff of the Libraries of the Royal Society Museum for the History of Science and Technology Science Museum and the Wellcome Institute for the History of Medicine all in London for their assistance Moreover most of the quotations are extracted from the biography of Young by G Peacock or from that by A Wood Those who may wish to pursue Thomas Young s contribution to their special area are encouraged to consult Wood first as his book is both relatively easy to find and is a gold mine of information collected over years and years of painstaking research

Lastly I note with pleasure the contribution to my own education by Dr R T Jones also a self educated genius who among other things first introduced me to the contributions of Thomas Young

Furthermore I hope and trust that the reader will appreciate my problem in attempting to cover the contributions of so diverse a man as Thomas Young in so brief a space A selection was required and that necessarily is a very personal matter

Heart rate levels and ventricular ectopic activity during cardiac rehabilitation

Maarten Simoons M D
Cees Lap M D
Jan Pool M D
With the technical assistance of Anja Roodenburg and Cecile van Gent
Rotterdam The Netherland

In many centers exercise programs have been developed for rehabilitation of patients after a myocardial infarction It has been recommended that candidates for participation should be screened in order to evaluate their motivation to eliminate undue risk and to evaluate the possible benefits of the program In particular several authors state that patients with frequent multiform or repetitive premature ventricular complexes (PVCs) should not be accepted for physical training unless the arrhythmia has been treated However in spite of the widespread experience with rehabilitation of cardiac patients little information is available on the actual incidence of arrhythmias during rehabilitation programs In one study heart rates and arrhythmias have been described during exercise tests and ambulatory monitoring including cardiac exercise classes However no separation was made between data during the exercise period and during other activities The present study was designed to address the following questions

1 Which heart rate levels are reached during rehabilitation of groups of patients with coronary artery disease?

2 How are these heart rates related to those during a symptom limited exercise test and during normal daily activities?

3 Which patterns of ventricular ectopic activity occur during the rehabilitation program?

4 Can these arrhythmias be predicted from either the exercise test or ambulatory monitoring during normal daily life?

Patient selection

Data were analyzed from 40 patients with coronary artery disease there were 39 males and one female between 32 and 65 years old Three other patients had to be excluded due to failure of the ambulatory ECG tape recording Thirty six patients were enrolled in the rehabilitation program after a myocardial infarction The interval between the infarction and the study was 3 to 6 months in six patients 7 to 12 months in 11 patients and 1 to 3 years in the remaining 19 patients Three patients were studied between 3 and 6 months after coronary bypass surgery Finally one patient was admitted to the program because of moderate angina pectoris At the time of the study patients had participated in the rehabilitation program between 1 and 6 months In Rotterdam patients can be referred to the rehabilitation program from several major hospitals and by private physicians In general medical therapy is provided by the referring physician Therefore indications for antiarrhythmic therapy and other drugs may vary between the participants in the rehabilitation program Actually 14 patients used no medication except anticoagulants or nitroglycerin Seventeen patients were on beta blockers seven used antiarrhythmic drugs six took digoxin and five patients received seda

tion The ECGs were analyzed at high speed by trained technicians using the Medilog system (Oxford Instruments) The 24 hours preceding the training and the actual training period were analyzed separately

A symptom limited exercise test was performed within the same week Medication was not changed during this period Workload on a calibrated bicycle ergometer was increased with steps of 10 Watts per minute until near exhaustion moderate angina pectoris or dyspnea Three ECG leads were continuously recorded on paper with paper speeds of 10 and 25 mm per second alternatingly

Premature ventricular complexes were classified as shown in Table I The part of the 24 hour recording during which each type of arrhythmia occurred was indicated semiquantitatively in five classes as shown in Table II absent occasional (less than 2 hours of ECG recording) episodic (2 to 12 hours) frequent (12 to 22 hours) and

Fig 6 Most severe grade of PVC (see *Fig 5*) in each patient during the rehabilitation program *(REHAB)* compared with the highest grade of PVC during 24 hours of normal daily activities

continuous (22 to 24 hours) Heart rates were measured from trend plots as shown in Fig 1 The mean heart rate was measured every hour as well as the highest heart rates reached during 24 hours and during rehabilitation

Results

In Fig 2 the heart rates during the 24 hours preceding rehabilitation are compared with the mean heart rates during rehabilitation In 37 patients the mean heart rate during rehabilitation was higher than the heart rate during any hour of the preceding day and night In addition the peak heart rates during rehabilitation exceeded those during 24 hour recording in 33 out of 40 patients as illustrated in Fig 3

With the rehabilitation session peak heart rates were found during jogging in 25 patients and during volleyball in the remaining 15 patients These data indicate that most patients exercised more vigorously during the rehabilitation program than at any moment of their normal activities However even during rehabilitation many patients did not reach the same heart rate level as during the exercise test which was performed within the same week The peak heart rates during the exercise test exceeded those during rehabilitation by 10 beats or more in 20 patients (Fig 4) while in five patients the peak heart rate during rehabilitation was 10 beats higher during rehabilitation than the heart rate during the exercise test

The performance during the exercise test averaged 92% (SD = 15%) of the predicted normal values Peak heart rates in those patients without beta blocker therapy averaged 89% (SD = 12%) of the age predicted maximum heart rate in each patient

The premature ventricular complexes observed during the symptom limited exercise test are presented in Table I PVCs occurred during all stages of the test Repetitive PVCs (code 4) were only observed during the highest workload and in the recovery period The occurrence of PVCs during 24 hours of normal daily activity are given in Table II In most patients PVCs were observed occasionally In six patients frequent PVCs were present The incidence of premature ventricular complexes during the symptom limited exercise test was similar to the results of other investigators In 22 out of 40 patients the PVCs during the stress test were of lower grade than those during 24 hours of ambulatory monitoring This again is in agreement with data published by

others[8,11] In two patients however a higher grade of PVC occurred during the exercise test Apparently these two methods disclose different information regarding the electrophysiological state of the myocardium[8]

The distribution of PVC during the rehabilitation session is shown in Table III In Figs 5 and 6 the data in each patient are compared under the three different conditions exercise test normal activities and rehabilitation program It is shown that the PVCs during rehabilitation could not be predicted from the exercise ECG The sensitivity for prediction of severe PVCs (grades 2 to 4) during rehabilitation from the exercise test is only 44% (four out of nine cases) while the specificity is 87% (27 out of 31 cases) as shown in Fig 5 On the other hand all nine patients with severe PVCs during rehabilitation were detected by ambulatory ECG recording (sensitivity 100%) at the cost of a poor specificity (20 out of 31 = 64%) as presented in Fig 6 No differences in ventricular ectopic activity were observed between the patients who took digitalis beta blockers or other antiarrhythmic drugs

Discussion

In the Rotterdam Rehabilitation Program patients are exercised in groups under medical supervision but without ECG monitoring The program consists of jogging walking calisthenics and ball games Many patients were able to perform in the program at similar levels of work as in the symptom limited exercise test on the bicycle ergometer (Fig 2) Most patients reached considerably higher heart rates during rehabilitation than during their other activities The occurrence of ventricular arrhythmias was not related to the level of physical activity as represented by the heart rate Most PVCs were observed during normal activities and fewer during the exercise test and during the rehabilitation program This may be due to the length of the ECG records since the majority of arrhythmias occurred during less than 2 out of 24 hour monitoring period (Table II) while the exercise test and the rehabilitation program had a duration of approximately 30 and 60 minutes respectively

It has been recommended that patients with frequent multiform or repetitive PVCs should not be accepted in a rehabilitation program However neither the exercise test nor ambulatory monitoring provided an accurate prediction of the type of PVC seen during the rehabilitation program five patients had multiform or repetitive PVCs during rehabilitation while no PVC or less than 5/minute occurred during stress testing (Fig 5) Thus the sensitivity of exercise tests for the prediction of higher grade PVCs during rehabilitation is low Ambulatory monitoring predicted all patients with PVCs during rehabilitation However it would be impractical to exclude patients with frequent multiform or repetitive PVCs on the 24 hour recording from a rehabilitation program since these arrhythmias occur in many post infarct patients at some time or other In fact in the present series 20 out of 40 patients should have been excluded according to such a criterion while only nine of these 20 developed grade 2 to 4 arrhythmias during the actual rehabilitation session (Fig 6) Since it appeared to be impossible to predict PVCs during rehabilitation from either the exercise ECG or the ambulatory tape recording we conclude that exclusion of patients from the rehabilitation program should not be based on the observation of higher grade PVCs per se It is likely that the risk of cardiac arrest or other cardiovascular incidents is greatest in those patients with extensive left ventricular impairment especially in those with a low physical capacity and with an inadequate heart rate or blood pressure response during exercise[1,11] Selection of patients by such criteria seems more appropriate than exclusion of all those patients who show higher grade arrhythmias during an exercise test

In the present investigation no life threatening arrhythmias occurred During our total experience of 5 years of cardiac rehabilitation in Rotterdam which involved 15 000 patient hours one patient developed ventricular fibrillation This patient was successfully resuscitated and subsequently underwent coronary bypass surgery No excess mortality was reported in a recent review by Haskell which covered 30 cardiac rehabilitation programs in the USA and Canada During more than 1 600 000 hours of supervised exercise 50 cardiac arrests were reported eight of which were fatal In addition five [illegible] fatal and [illegible] fatal myocardial infarctions [illegible] as well as four other fatal cardiovascular accidents [illegible] exclusion of seven deaths [illegible] rehabilitation programs in a small group of patients [illegible] mortality rate was 1 per [illegible] patient [illegible] which corresponds to an a[illegible]al mortal[illegible]

4 1% It should be noted however that 42 patients with cardiac arrests were successfully defibrillated This indicates that the risk of cardiac arrest during rehabilitation is considerably higher than the risk during other activities in spite of the selection criteria which were applied by the various centers Therefore promotion of exercise programs for patients with coronary artery disease should be avoided unless the experienced personnel and appropriate equipment are immediately available This risk of cardiac rehabilitation can be covered effectively by personnel who have been trained in cardiopulmonary resuscitation

Summary

The heart rate levels and the incidence and types of premature ventricular complexes (PVCs) during the rehabilitation of 40 patients with coronary artery disease were compared with those during 24 hour ambulatory monitoring and during a symptom limited exercise test Thirty six patients were studied 3 months or later after a myocardial infarction and four patients were studied after coronary bypass surgery The last patient suffered from moderate angina pectoris Peak heart rates during rehabilitation exceeded those during other activities in 34 out of 40 patients Half of the patients reached even higher heart rate levels during the exercise test Twenty three patients had PVC during rehabilitation frequent multiform or repetitive PVC occurred in nine of these During the exercise test 24 patients had PVCs while PVCs were observed on the ambulatory tape recording in 34 patients Frequent multiform and repetitive PVCs occurred in eight patients during exercise testing and in 20 patients during monitoring No relation was found between either the incidence or the type of PVC in individual patients under these three condition Thus selection of patients with a high risk for arrhythmias during rehabilitation is not feasible by either exercise testing or ambulatory tape recording

Parenteral lidocaine is particularly effective in the acute control of ventricular ectopy in the early post myocardial infarction period However chronic oral therapy has not proven feasible in part because of a short half life of elimination In addition lidocaine undergoes extensive first pass hepatic extraction[1] leading to accumulation of the de-ethylated metabolites monoethylglycinexylidide (MEGX) and glycinexylidide (GX) these contribute to side effects during oral therapy[2] Tocainide is a congener of lidocaine (Fig 1) which has been shown to have antiarrhythmic efficacy in man[3] when given orally It is particularly suitable for long term use since absorption after oral administration is virtually complete and its long half life of elimination (12 to 22 hours) allows dosing on an eight to 12 hourly basis We report our experience with the use of tocainide in a group of patients whose complex ventricular arrhythmias could not be successfully treated with the standard therapeutic regimens

Materials and methods

Patients were studied in the coronary care unit or the Clinical Research Center of Vanderbilt University Hospital All those who had received trials of quinidine procainamide propranolol and disopyramide without satisfactory response were candidates for this trial Plasma concentrations of quinidine procainamide and propranolol were routinely monitored These agents were considered ineffective if

1 Computerized analysis of 12 to 24 hours of ECG documented lack of sustained (>60%) arrhythmia suppression and persistence of symptoms with plasma concentrations in the range usually associated with efficacy or

2 Acute intravenous or oral dosing with computerized analysis of ECG data pre and post therapy showed no change in the arrhythmia with the attainment of plasma concentrations in the usual therapeutic range or

3 Patients developed intolerable side effects with lack of suppression of their arrhythmia at lower dosages or

4 Patients developed allergic or immunologic side effects which necessitated the discontinuation of therapy or

5 Therapy with a given agent was contraindicated

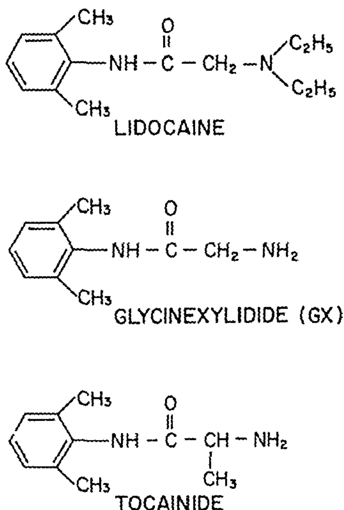

Fig 1 Chemical structures of lidocaine glycinexylidide a lidocaine metabolite and tocainide

Lidocaine responsiveness was assessed in all patients This was done either by (1) a loading infusion at 120 µg/Kg /minute for 25 minutes (15 patients) or (2) the assessment of lidocaine re sponsiveness by the review of rhythm strips and charts after standard acute therapy in a CCU setting most often 100 to 150 mg intravenously followed by an infusion of 1 to 4 mg /minute (four patients) Arrhythmias were considered respon sive to lidocaine if 90% or more ventricular ectopic depolarizations (VEDs) and all complex arrhyth mias were abolished without symptoms Such strict criteria were necessary because of the short control periods used Plasma concentrations when available were monitored with either approach

Patients with symptomatic arrhythmias resis tant to standard therapy (as described above) regardless of lidocaine response were asked to participate in the evaluation of the use of tocain ide for control of refractory ventricular arrhyth mias Patients giving informed consent were then withdrawn from other antiarrhythmic therapy (usually lidocaine) if possible After 24 to 48 hours of ECG recording while receiving placebo tocain ide was begun at low dosages (200 to 400 mg orally every 8 to 12 hours) Each dosage level was continued until steady state was achieved (36 to 48 hours) at which time 12 hour ECG tapes and plasma for trough tocainide concentration were obtained and the daily dosage was increased if necessary The dosage was increased to the point of arrhythmia suppression or the development of side effects Transient dose related side effects were controlled if possible by the adoption of lower doses at shorter dosing intervals or by the administration of medication with a meal or snack

In this highly selected group of patients chronic oral therapy with tocainide or the con ventional agents described above was declared successful if a 60% decrease in VED frequency was documented as well as suppression of symp tomatic ventricular tachycardia (VT) while the patient was ambulatory in hospital In order to avoid misinterpreting spontaneous variation in arrhythmia frequency for a drug response com parisons were made between pre drug placebo control data and all dosages of tocainide to ascertain if a dose response relationship was pres ent As well therapy with tocainide was discon tinued after the trial to detect a return to baseline arrhythmia frequency and severity in those who appeared to respond this was omitted in patients whose clinical status was felt to be too unstable to permit such a maneuver

ECG data were recorded on eight track tape using a Honeywell model 96 FM recorder Tapes were then analyzed by a blinded computer opera tor using a PDP 11/40 laboratory minicomputer and a previously described and verified program which counts VEDs and runs of VT (≥ 3 VEDs in a row rate ≥ 100/minute) using a template matching algorithm

Patients whose arrhythmia was responsive to tocainide were discharged on the dosage regimen providing maximum benefit and a minimum of side effects and were followed as out patients at weekly to monthly intervals Routine electrocar diograms hematology (Coulter counter) bio chemistry (SMAC) and antinuclear antibody (ANA) tests (Meloy Kit 6715 Electronic Drive Springfield VA) were performed at each visit

Emergency DC-cardioversion required in the past

Rhythm control was evaluated by 30 to 120 minute rhythm strips run at 1 0 mm /sec by periodic 24 hour Holter recording and by the presence or absence of symptoms of VT

Blood samples for determination of plasma tocainide concentration were obtained in the 30 minutes prior to a dose and 60 to 90 minutes after a dose for the assessment of plasma concentrations associated with therapeutic effects and with possible adverse effects Following the addition of glycinexylidide as an internal standard plasma was extracted into methylene chloride at an alkaline pH Aliquots were then injected into a μBondapak C column (3 9 × 300 mm) The analysis used a high performance liquid chromatograph (Waters Associates Milford Mass) the flow rate of the mobile phase (water methanol acetic acid (500 100 15 (v /v /v)) was 1 5 ml / minute at ambient temperature Eluate was monitored for UV absorption at 254 nm (spectrophotometer model 440 Waters Associates) Samples of drug free plasma to which internal standard and varying amounts (0 to 15 μg/ml) of tocainide had been added were used to prepare a standard curve relating peak height ratio (tocainide internal standard) to tocainide concentration Peak height ratios from patient samples were then used to determine tocainide concentration The coefficient of variation was 8 9 to 9 6% for concentrations ≥ 10 μg/ml at lower concentrations (≤ 5 μg/ml) it rose to 21 6 to 23% The sensitivity of this method allowed detection of concentrations of tocainide ≥ .5 μg/ml Samples from patients being treated with quinidine procainamide disopyramide phenytoin propranolol digoxin warfarin hydrochlorothiazide furosemide diazepam flurazepam aspirin and acetaminophen produced no interfering peaks Data from patients who had received lidocaine within the previous 24 hours were not used because of potential interference by GX

Results

Nineteen patients participated in this study (Table I) The ages ranged from 28 to 69 years 12 were female Eight had coronary artery disease one had hypertensive heart disease two had mitral valve prolapse and two had congestive cardiomyopathies the remaining six had ventricular arrhythmias with no identifiable heart dis-

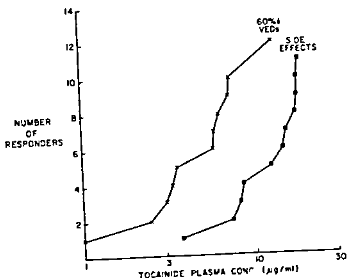

Fig 2 Relationships between the cumulative number of patients demonstrating a response (arrhythmia suppression or side effects) and tocainide concentration

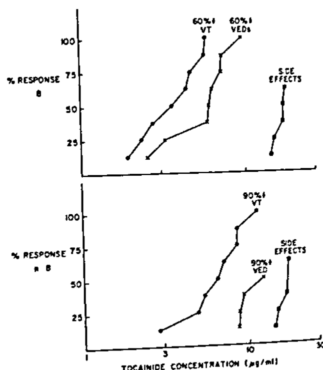

Fig 3 Dose-response relationships for VED suppression VT suppression and side effects among the eight patients with frequent VT

ease All six had normal echocardiograms QTc intervals (range 360 to 420 msec) and physical examinations Follow up ranged from 2 to 15 years and neither congestive heart failure nor angina developed in any patient Symptoms in the 19 patients ranged from palpitations to syncope cerebrovascular accidents and cardiopulmonary arrests All had frequent VEDs Fifteen had a history of ventricular tachycardia and four of these had previously documented ventricular fibrillation

Fifteen of the 19 responded to tocainide (as defined above) All 13 patients whose arrhythmia was sensitive to lidocaine were in this group while only two of the six patients resistant to lidocaine responded to tocainide ($P < 0.005$ Fisher s exact test) Lidocaine resistance was documented in four patients by the absence of change in arrhythmia frequency and by the presence of typical side effects during the infusion protocol after a mean dose of 270 mg (range 180 to 390 mg) over 25 minutes The fifth patient had no change in arrhythmia frequency and a plasma concentration of 5 8 µg/ml following the lidocaine infusion and the sixth patient was judged lidocaine resistant following review of her CCU data showing no change in arrhythmia frequency during prolonged infusions of 2 to 3 mg /minute

Dose response plots relating reduction in VED frequency (from placebo baseline) to trough tocainide concentration (at steady state) could be constructed in 12 (patients 1 to 12) responders Placebo baseline recordings were not obtained in the other three (patients 13 to 15) but tocainide was effective in abolishing their frequents runs of symptomatic VT All of these 12 patients demonstrated incremental reductions in VED frequency as the plasma concentration of tocainide increased The plot relating plasma concentration to aggregate response in the group is shown in Fig 2 a curve relating concentration to the observed incidence of side effects (see below) for the entire group of 19 patients is also shown in Fig 2. Eight of these twelve (patients 1 to 8) had frequent runs of VT (≥ 2 episodes per hour) during placebo therapy Fig 3 shows the relationship among VED reduction VT reduction and side effects in this group

Return of arrhythmia to 88%(±SE 18) of placebo control frequency was observed in 11 of the 15 responding patients (Fig 4) This maneuver was not attempted in three (patients 8 13 14) and in a fourth (patient 6) VT recurred only hours after she missed a dose of tocainide necessitating reinstitution of therapy Concurrent antiarrhythmic therapy was undertaken in two patients In one a partial response to tocainide was seen initially and a greater degree of arrhythmia control was established with the addition of

procainamide This patient had had no response to procainamide alone and so was discharged on the two agents together he subsequently died (see below) A second patient underwent tocainide dose ranging while receiving propranolol for paroxysmal atrial tachycardia She developed tremor and nausea and was not judged to have an antiarrhythmic response to tocainide Four patients were also treated with digoxin three for control of congestive heart failure and one for paroxysmal atrial fibrillation

Side effects were observed in 11 patients (58%) during tocainide therapy and most often occurred immediately following a dose taken on an empty stomach These side effects affected primarily the central nervous system (ataxia paresthesias lightheadedness nervousness and tremor) the other dose related side effects were gastrointestinal (primarily nausea) In four patients the margin between effective and excessive plasma concentrations was so narrow that out patient treatment had to be stopped

Chronic out patient therapy with tocainide was undertaken in 12 of the 15 responders three could not be discharged on drug (two developed drug allergy in hospital and one died) The discharge regimens were 800 to 2 400 mg /day (mean 1 600) in two to three divided doses Three additional deaths have occurred (see below) four patients have had to stop therapy because of prominent central nervous system side effects at effective antiarrhythmic dosages and three further cases of drug allergy have occurred Maintenance of arrhythmia control was documented at the regularly scheduled clinic visits in all patients (including those who subsequently died) symptoms previously related to the arrhythmia did not recur Two (patients 1 and 8) continue on treatment and are asymptomatic at one and four years respectively Drug withdrawal and substitution of placebo has been carried out three times over the 4 years patient 1 has been on treatment on each occasion return of ventricular tachycardia was documented

Four patients died during tocainide therapy One was a 35 year old man with a congestive cardiomyopathy who died in hospital after the initial trial of tocainide his symptomatic runs of VT were suppressed with treatment leaving isolated VEDs and couplets He died in cardiogenic shock while awaiting heart transplantation

The second patient was a 47 year old man with severe coronary artery disease and recurrent ventricular fibrillation initially controlled on tocainide Two weeks after discharge on tocainide he developed atrial tachycardia followed shortly by ventricular fibrillation that required D C cardioversion and was eventually controlled with a combination of procainamide and tocainide After a total of 3 months on tocainide while at home he developed increasing symptoms of congestive heart failure and had another cardiopulmonary arrest He was taken to his local hospital where ventricular fibrillation was documented and he could not be resuscitated Postmortem tocainide plasma concentration was in his usual therapeutic range (10 0 μg/ml) but procainamide (11 4 μg/ml) and N acetylprocainamide (19 9 μg/ml) were well above his usual levels

The third patient who died was a 52 year old woman who died suddenly at home after 5 months of therapy She had been seen in the clinic four days before with tocainide levels in her usual range and good arrhythmia control but had stopped taking her medications the day prior to her sudden death

The fourth patient was a 57 year old man with coronary artery disease and congestive heart failure He had been receiving tocainide for 13 months After developing increased angina and dyspnea at home he died suddenly autopsy

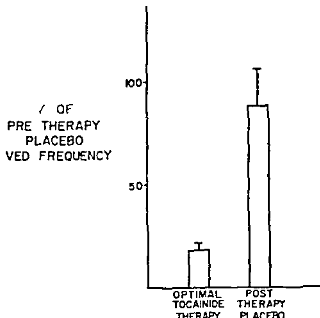

Fig 4 Comparison of VED frequency at the end of tocainide dose ranging and following tocainide withdrawal (mean ± SE)

showed a coronary artery dissection which was thought to have precipitated a fatal arrhythmia Tocainide concentration was 10 9 μg/ml post mortem

Five patients developed allergic symptoms during tocainide therapy In four these occurred within six weeks of the initial dose while a rash developed in the fifth after four months on therapy Two patients had pruritic rashes only one patient had pruritus without a rash a fourth had rash pruritus night sweats and eosinophilia and the fifth had fever and night sweats All symptoms resolved promptly with withdrawal of tocainide and in no case could other agents be implicated as a possible cause

Biochemical and hematological screening tests showed no adverse reactions during tocainide therapy One patient entered the trial with a strongly positive ANA test which had developed during procainamide therapy over the previous 8 months she was symptomatic with arthritis and pulmonary infiltrates The ANA have persisted during the year she has been taking tocainide although the symptoms and infiltrate have resolved Two other patients developed ANA shortly after starting tocainide but in both cases prior procainamide therapy could be implicated and in neither did symptoms of lupus erythematosus develop

Discussion

There is evidence that chronic therapy with beta blocking agents anti platelet agents ' or phenytoin might reduce the incidence of sudden death in a high risk population Procainamide and quinidine have been studied by Myerburg and colleagues in survivors of ventricular fibrillation maintenance of serum levels in the therapeutic range appeared to be the major determinant of the incidence of recurrent fibrillation rather than isolated VED frequency The high incidence of side effects during therapy with these agents and the question of what defines a "therapeutic concentration in this context have not yet been addressed One possibility is that while VEDs may be unchanged during adequate therapy more complex arrhythmias may be disproportionately decreased A tendency toward such a reduction was seen in the study of Myerburg and associates although statistical significance was not achieved We have recently shown that a 70% decrease in VED frequency during propranolol therapy was associated with abolition of VT [11] The similar disproportionate reduction in VT frequency as plasma concentration increased that we have now demonstrated with tocainide suggests that this phenomenon may occur often

The definition of the therapeutic window i.e., the range defined by plasma concentrations associated with effective and with excessive drug actions is arbitrary The degree of acceptable risk of side effects varies among individuals (and populations) as does the end point used to designate response (Fig 3) In this study group 25% of the 19 patients developed side effects at plasma tocainide concentrations ≥ 11 μg/ml, while 25% of those responding (with ≥ 60% VED suppression) did so at plasma concentrations ≥ 3 μg/ml (Fig 2) Thus using arbitrary 25% limits on acceptable degrees of efficacy and toxicity the range 3 to 11 μg/ml could be termed the therapeutic window for tocainide in this group

Recent observations have increased awareness of the problem of spontaneous variation in VED frequency Morganroth and colleagues' advocated use of prolonged recordings of ECG data during control and drug periods to avoid misinterpreting this spontaneous variation Virtual abolition of arrhythmias is needed to demonstrate efficacy with short periods of observation such as acute response to lidocaine However lesser changes in arrhythmia frequency may be attributed to drug treatment if longer periods of observation are undertaken The prolonged periods of observation used in this study as well as the demonstration of dose response relationships showed that tocainide had antiarrhythmic activity in these patients Re-emergence of arrhythmia during substitution of placebo for active therapy provided additional evidence that this was a true drug effect In the three patients in whom tocainide was not withdrawn the dramatic clinical improvement (no further cardic arrests) during tocainide dose ranging as well as increasing VED suppression made it unlikely that the observed response was fortuitous

Acute sequential drug testing has been proposed as an approach to the patient with serious symptomatic arrhythmias ' However translation of the results of acute drug testing to chronic oral therapy is not always possible For instance testing with intravenous propranolol for VED suppression does not predict response to oral

therapy.[14] Acute drug testing does not permit accumulation of metabolites which may have antiarrhythmic activity of their own; response to procainamide challenge does not predict subsequent response to N-acetylprocainamide.[15] We have now shown that response to acute challenge with one agent, lidocaine, predicts response to a different (although structurally related) agent, tocainide, in patients whose arrhythmias are not controlled by conventional oral drug therapy. The fact that the spectrum of side effects seen during the use of these two agents is also similar may reflect the structural similarity among lidocaine, its metabolites, and tocainide.

Trials of tocainide in populations of patients who did not exhibit the resistance to standard agents shown by this group have had a 66 to 71% response rate.[1, 17] Winkle and colleagues and Ryan and associates[19] have reported their experience with patients resistant to conventional therapy; the initial response rates were also 70%. Three of the 17 patients reported by Winkle and colleagues died on therapy. No deaths were recorded among those treated with tocainide by Ryan and co-workers, although that group also noted a high incidence (70%) of dose-related symptoms and two cases of drug-related rash (6.7%).[1, 9]

The high mortality rate in this and other reports of chronic tocainide therapy reflects the underlying severity of the rhythm disturbance and basic disease process among these highly selected groups of patients. It may also be that reduction in VED (or VT) frequency does not decrease the risk for sudden death despite an association between the two. However, even during short periods of therapy, these highly selected patients often note improvement in other VED-related symptoms such as dyspnea on exertion or recurrent syncope. In such patients, the only clinically attainable end point may be suppression of symptoms even after systematic trials of multiple conventional and investigational agents.[1]

Trials of new antiarrhythmic agents in this setting are biased by the referral and selection processes. The true place of tocainide in the therapy of ventricular arrhythmias and sudden death prophylaxis is not yet known. It provided long-term life-saving treatment in two of our 19 patients. In this population of patients with resistant arrhythmias, the use of tocainide was associated with a good initial response rate but a narrow toxic therapeutic ratio and a high incidence of drug allergy which limited therapy in many patients.

Summary

Tocainide, a congener of lidocaine, was used to treat symptomatic ventricular arrhythmias in 19 patients resistant to or unable to tolerate conventional agents. In this highly selected group, 15 showed good initial responses to oral therapy. Ventricular tachycardia was suppressed to a greater extent than isolated ventricular ectopic depolarizations at any plasma concentration, and upward dose ranging showed progressive suppression of both. Arrhythmia responsiveness to lidocaine was found to be an excellent predictor of tocainide response.

Of the 15 responders, one died 24 hours after stopping therapy, three died while receiving tocainide, nine stopped because of adverse reactions (five allergic), and two continue on therapy at 1 and 4 years. We conclude that tocainide is an effective agent for the short-term suppression of ventricular arrhythmias, particularly ventricular tachycardia sensitive to lidocaine, but a high incidence of adverse effects limits its application to chronic therapy in many patients.

The electrophysiologic effects of intravenous lidocaine in the Wolff-Parkinson-White syndrome

Peter A Barrett M D F R A C P
Michael M Laks M D
William J Mandel M D
Iwao Yamaguchi M D
Los Angeles Calif

In spite of the progress in our understanding of the pathophysiology of the Wolff Parkinson White syndrome since its description in 1930 [1] knowledge of the most appropriate medical therapy is still inadequate Clinically it is difficult to assess therapy in the Wolff Parkinson White syndrome as the tachycardias are variable and paroxysmal [1] and because patients may historically overstate or understate the incidence of palpitations [2, 8] Knowledge is accumulating however with the increasing number of electrophysiologic assessments of the effects of therapy in this syndrome [9]

Isolated clinical case reports[1] have indicated that intravenous lidocaine may be effective therapy for supraventricular tachyarrhythmias with accessory pathway conduction Lidocaine in fact has been reported as being extremely valuable [1, 2] in this regard because of a depressant effect on accessory pathway conduction Such supraventricular tachyarrhythmias may resemble ventricular tachyarrhythmias which may also occur in the WPW syndrome [5, 8] and lidocaine is known to be effective therapy for these [3] Accordingly in an acute situation differentiation between supraventricular tachyarrhythmias with accessory pathway conduction and ventricular tachyarrhythmias may be academic The purpose of this study therefore was to obtain an electrophysiologic assessment of lidocaine in the WPW syndrome

Material

Twelve patients with the WPW syndrome were studied One had coronary heart disease and another had Ebstein s anomaly There were 10 males The ages of the patients ranged from 15 to 63 years with a mean of 33 ± 5 years (mean ± standard error of the mean) Seven patients had Type A[3] WPW syndrome and in one of these the WPW anomaly was intermittent Five patients had Type B[32] WPW syndrome Tachycardia had been present in all patients for a mean of 11 ± 3 years with a mean frequency of approximately monthly occurrence

Methods

The studies were performed in the fasting state after obtaining informed consent The patients had not received any medication for at least 48 hours prior to study Intracardiac electrograms were obtained by standard techniques [33] and were recorded on a multichannel photographic recorder with paper speeds between 25 and 100 mm / sec (Electronics for Medicine Model DR 12) Multiple standard electrocardiographic leads were recorded with high right atrial low right atrial coronary sinus and His bundle electrograms The protocol used was as previously described [13, 31]

During sinus rhythm the heart rate and P delta AH and HV intervals were measured High right atrial pacing[1] was performed at

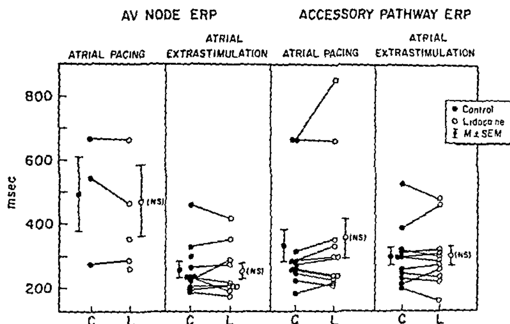

Fig 1 Anterograde AV effective refractory period *(ERP)* of the AV node and the accessory pathway as determined by the atrial pacing and extrastimulus techniques Statistical analysis (*NS* = no significant change) relates only to those cases where determinations were able to be made in both the control state *(C)* and after lidocaine *(L)* Results are expressed as mean ± standard error of the mean

rates to assess anterograde AV refractoriness A measurement of anterograde AV node effective refractory period was obtained by taking the cycle length of the maximum rate of atrial pacing where 1 1 AV node conduction was preserved The anterograde accessory pathway effective refractory period was taken as the cycle length of the maximum rate of atrial pacing where 1 1 accessory pathway conduction was preserved The atrial extra stimulus technique[35, 36] during atrial pacing was used to determine the antero grade AV node and accessory pathway effective refractory periods and the atrial muscle effective refractory period Right ventricular apical pacing was performed at increasing rates to assess ventriculoatrial (VA) conduction The VA conduction time was measured from the ventricular stimulus artifact to the onset of the right septal atrial, coronary sinus and high right atrial electrograms A measurement of the VA effective refractory period was taken as the cycle length of the maximum rate of ventricular pacing where 1 1 VA conduction was preserved The ventricular extrastimulus technique during ventricular pacing was used to determine the VA and the ventricular muscle effective refractory periods

The initiation of tachycardia by these maneuvers[34, 40] was noted The rate and VA conduction time in the case of re entry tachycardia and the shortest RR interval of the ventricular response in the case of atrial fibrillation were measured

The above procedures were repeated with the catheters in the same positions after an intravenous bolus of lidocaine 1 mg/kg administered over 30 seconds The repeat studies begun 1 minute after the bolus were completed in all patients within 15 minutes Statistical evaluation was performed with Student s t test for paired samples

Results

Effective refractory periods

Anterograde AV node effective refractory period The anterograde AV node effective refractory period was able to be determined by means of the atrial pacing technique in only three patients in the control state and in five after lidocaine This was because 1 1 accessory pathway conduction usually persisted at the maximum rate of atrial pacing with 1 1 AV conduction The point of failure of 1 1 AV node conduction therefore could not be readily determined as the His deflection was then obscured in the ventricular depolarization wave of the His bundle electrogram In three patients therefore the mean anterograde AV node effective refractory period as determined by this technique decreased by 5% after lidocaine from 495 ± 116 msec to

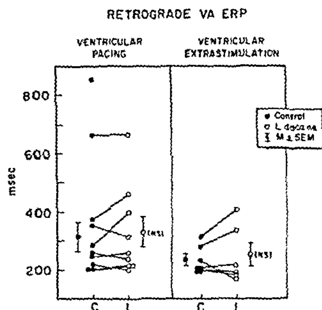

Fig 2 Retrograde VA effective refractory period *(ERP)* as determined by the ventricular pacing and extrastimulus techniques

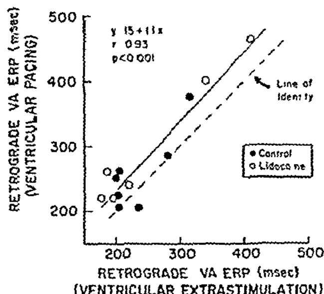

Fig 3 Linear relationship close to the line of identity between the retrograde VA effective refractory period *(ERP)* as determined by the ventricular pacing and extrastimulus techniques

472 ± 110 msec without statistical significance (p = 0 5) (Fig 1)

The anterograde AV node effective refractory period was able to be determined by means of the atrial extrastimulus technique in 10 patients in the control state and after lidocaine In two patients with increasing prematurity of atrial extrastimuli in the control state accessory pathway conduction persisted to the point of failure of AV conduction In these cases the point of failure of AV node conduction could not be readily determined as the His deflection was obscured In these 10 patients therefore the mean anterograde AV node effective refractory period as determined by this technique decreased by 1% after lidocaine from 258 ± 26 msec to 256 ± 25 msec without statistical significane (p = 0 9) (Fig 1)

Anterograde accessory pathway effective refractory period The anterograde accessory pathway effective refractory period was able to be determined by means of the atrial pacing technique in 11 patients in the control state and after lidocaine In one patient with intermittent WPW syndrome delta were not present at the time of the study In these 11 patients the mean anterograde accessory pathway effective refractory period as determined by this technique increased by 7% after lidocaine from 334 ± 51 msec to 359 ± 63 msec without statistical significance (p = 0 2) (Fig 1)

In these 11 patients the mean anterograde accessory pathway effective refractory period as determined by the atrial extrastimulus technique increased by 1% after lidocaine from 302 ± 28 msec to 305 ± 29 msec without statistical significance (p = 0 8) (Fig 1)

Retrograde VA effective refractory period The retrograde VA effective refractory period was able to be determined by means of the ventricular pacing technique in 10 patients in the control state and nine after lidocaine One to one VA conduction was absent at all rates of ventricular pacing in one patient in the control state and in two after lidocaine so that the exact value of the VA effective refractory period could not be determined in these instances The technique was not performed in another patient In nine patients therefore the mean retrograde by 6% after lidocaine from 314 ± 49 msec to 332 ± 51 msec without statistical significance (p = 0 3) (Fig 2)

The retrograde VA effective refractory period was able to be determined by means of the ventricular extrastimulus technique in seven patients in the control state and in six of these patients after lidocaine It was not performed in the three instances of absent 1 1 VA conduction or in two other instances In six patients there

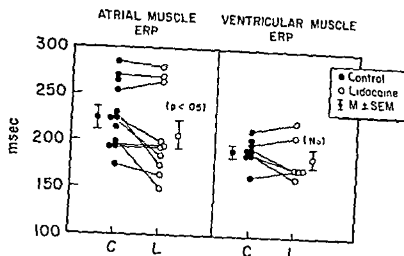

Fig 4 Atrial and ventricular muscle effective refractory periods (FRP) as determined by the extrastimulus technique

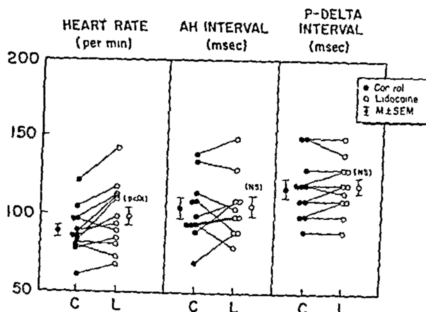

Fig 5 Heart rate and anterograde AV conduction times (*AH* and *P delta* intervals) during sinus rhythm

fore the mean VA effective refractory period as determined by this technique increased by 6% after lidocaine from 240 ± 19 msec to 254 ± 40 msec without statistical significance ($p = 0.6$) (Fig 2)

The retrograde VA effective refractory period was estimated by both the ventricular pacing and extrastimulus techniques in 13 instances in the control state and after lidocaine There was a significant linear correlation between the two techniques ($r = 0.93$ $p < 0.001$) and the line drawn from the linear regression equation was close to the line of identity (Fig 3)

Atrial and ventricular muscle effective refractory periods The atrial muscle effective refractory period was determined by means of the atrial extrastimulus technique in 12 patients in the control state and in 10 after lidocaine In 1 patients therefore the mean atrial muscle effective refractory period significantly decreased by 8% after lidocaine from 226 ± 11 msec to 208 ± 15 msec ($p = 0.04$) (Fig 4)

The ventricular muscle effective refractory period was determined by means of the ventricular extrastimulus technique in eight patients in the control state and in six after lidocaine In six patients therefore the mean ventricular muscle effective refractory period decreased by 3% after lidocaine from 193 ± 7 msec to 188 ± 10 msec without statistical significance ($p = 0.5$) (Fig 4)

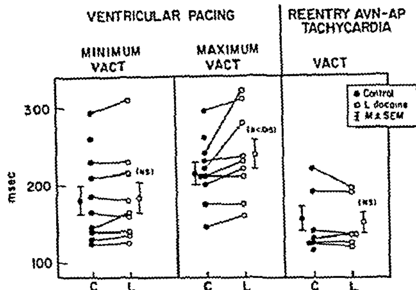

Fig 6 Retrograde VA conduction time (CT) during ventricular pacing (minimum and maximum) and during reentry AV node accessory pathway tachycardia

Conduction times The mean heart rate of the 12 patients significantly increased by 11% after lidocaine from 89 ± 4/minute to 99 ± 6/minute (p = 0 01) (Fig 5)

Anterograde AV node conduction time The AH interval or the anterograde AV node conduction time was able to be determined during sinus rhythm in 11 patients in the control state and in 10 after lidocaine In three instances the His deflection was obscured in the delta wave of the His bundle electrogram In 10 patients therefore the mean anterograde AV node conduction time during sinus rhythm increased by 2% after lidocaine from 105 ± 7 msec without statistical significance (p = 0 7) (Fig 5)

Anterograde accessory pathway conduction time The P delta interval an estimate of the anterograde accessory pathway conduction time was able to be determined during sinus rhythm in all patients in the control state and after lidocaine except for the patient in whom delta waves were absent at the time of study In 11 patients therefore the mean anterograde accessory pathway conduction time during sinus rhythm increased by 2% after lidocaine from 118 ± 6 msec to 120 ± 5 msec without statistical significance (p = 0 5) (Fig 5)

Retrograde VA conduction time In nine patients the mean minimum VA conduction time at the slowest rate of ventricular pacing with 1 1 VA conduction increased by 2% after lidocaine from 181 ± 19 msec to 184 ± 20 msec without statistical significance (p = 0 2) (Fig 6) The mean maximum VA conduction time at the maximum rate of ventricular pacing with 1 1 VA conduction significantly increased by 11% after lidocaine from 214 ± 13 msec to 238 ± 19 msec (p = 0 03) (Fig 6)

During the studies re entry AV node accessory pathway tachycardia with anterograde AV node and retrograde accessory pathway conduction developed in seven patients in the control state and in six after lidocaine In six patients therefore the mean retrograde accessory pathway conduction time during re entry AV node accessory pathway tachycardia decreased by 3% after lidocaine from 155 ± 16 msec to 150 ± 14 msec without statistical significance (p = 0 3) (Fig 6)

Tachycardia initiation

Incidence and rate of tachycardia Re entry AV node accessory pathway tachycardia was initiated in seven patients in the control state and in six after lidocaine In six patients therefore the mean rate of the tachycardia increased by 2% after lidocaine from 196 ± 10/minute to 200 ± 9/minute without statistical significance (p = 0 4) (Fig 7)

Re entry accessory pathway AV node tachycardia with anterograde accessory pathway and retrograde AV node conduction was initiated in one patient in both the control state and after lidocaine The rate of the tachycardia remained unchanged at 207/minute (Fig 7)

Atrial fibrillation with accessory pathway con

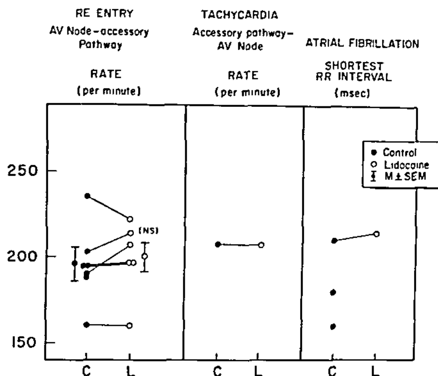

Fig 7 Incidence and rate of tachycardias initiated during the electrophysiologic studies

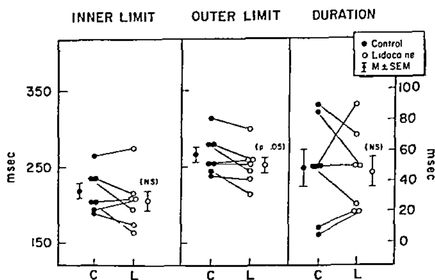

Fig 8 Features of the "tachycardia zone" or the zone of atrial extrastimuli that initiate reentry tachycardia

duction developed in three patients in the control state and in one of these after lidocaine In the latter patient the shortest RR interval of the ventricular response increased by 2% after lidocaine from 210 msec to 215 msec (Fig 7)

Tachycardia zone Re entry tachycardia of either type was initiated by atrial extrastimuli in seven patients in the control state and after lidocaine The tachycardia zone or the zone of coupling intervals of atrial extrastimuli that initiate tachycardia may be described in terms of its inner and outer limits and its duration The mean inner limit of the tachycardia zone decreased by 6% after lidocaine from 219 ± 10 msec to 206 ± 13 msec without statistical significance (p = 0 2) The mean outer limit significantly decreased by 5% after lidocaine from 267 ± 10 msec to 253 ± 10 msec (p = 05) The mean duration of the tachycardia zone decreased by 6% after lidocaine from 49 ± 12 msec to 46 ± 10 msec without statistical significance (p = 0 8) (Fig 8)

Anterograde accessory pathway AV node effective refractory period difference. The difference between the anterograde accessory pathway and AV node effective refractory periods has been implicated as a factor in the tendency to develop re-entry tachycardia.[10] This relationship is illustrated in Fig. 9. It resembles a parabola with an optimal anterograde accessory pathway AV node effective refractory period difference for the initiation of re-entry tachycardia by atrial extrastimuli in these patients of approximately 40 msec. When this difference is less than or greater than approximately 40 msec, tachycardia initiation by atrial extrastimuli becomes progressively less likely. Where this value could be calculated, it was removed from its optimal value by 25 ± 3 msec in the control state (10 patients) and by 26 ± 6 msec after lidocaine (nine patients).

Discussion

In most cases tachycardia in the WPW syndrome occurs on the basis of a re-entry circuit formed by the atrial muscle, the AV node, the His-Purkinje system and ventricular muscle, and the accessory pathway. ⁴ Its direction is usually anterograde (across the AV node accessory pathway tachycardia) so that the QRS complexes are normal, but occasionally it is reversed (re-entry accessory pathway AV node tachycardia) so that the QRS complexes are bizarre, consisting of pure delta waves. Occasionally atrial fibrillation and flutter may occur, generally with accessory pathway conduction, so that the QRS complexes are usually bizarre.[5] Rarely ventricular fibrillation and sudden death may occur, being more likely in those patients with paroxysmal atrial fibrillation. Even the former tachycardias, however, may produce significant hemodynamic impairment requiring urgent therapy. Moreover, (1) re-entry AV node accessory pathway tachycardia may be conducted with aberrant intraventricular conduction and so may resemble ventricular tachycardia, (2) atrial fibrillation with accessory pathway conduction may also resemble ventricular tachycardia if the irregular ventricular response characteristic of atrial fibrillation is not noted, and (3) re-entry accessory pathway AV node tachycardia and atrial flutter with accessory pathway conduction and a regular ventricular response may be indistinguishable from ventricular tachycardia.

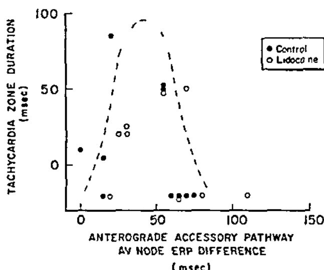

Fig. 9. Parabolic relationship between the difference in the anterograde effective refractory periods *(ERP)* of the accessory pathway and the AV node and the duration of the tachycardia zone. A tachycardia zone duration of 0 means that there was only one coupling interval of atrial extrastimuli that initiated reentry tachycardia. Points below this are instances where there was no tachycardia initiation by atrial extrastimuli.

Lidocaine is known to be effective in ventricular tachyarrhythmias ' and has been said to be extremely valuable in the WPW syndrome for supraventricular tachyarrhythmias with accessory pathway conduction, ' suggesting that lidocaine should be administered in either case. Nevertheless, as the tachycardias of the WPW syndrome are variable and paroxysmal, it is difficult to ascribe to the administration of a drug what may have occurred spontaneously. Because of this and because of possible additional effects of lidocaine, this electrophysiologic study was undertaken.

For a drug to be effective intravenously as acute therapy for the tachycardias of the WPW syndrome, it should act on part or all of the re-entry circuit in one or both directions so as to (a) terminate or decrease the rate of the re-entry tachycardias or (b) decrease the rate of the ventricular response in atrial fibrillation and flutter in the case of depression of the accessory pathway, or it should act on the atrial or ventricular muscle in such a way as to terminate atrial fibrillation or flutter or ventricular fibrillation.

Anterograde AV conduction. Lidocaine did not significantly increase the mean anterograde effective refractory periods of the AV node or the accessory pathway as determined by atrial pacing or extrastimulation. Accordingly, it is not likely to terminate the re-entry tachycardias by

this mechanism or decrease the rate of the ventricular response in atrial fibrillation

Rosen and colleagues[9] reported an increase in the anterograde accessory pathway effective refractory period as determined by atrial pacing in four of six patients and as determined by atrial extrastimulation in one of two patients after the intravenous administration of lidocaine in doses similar to those used in our patients Some of our patients also developed an increase in the antero grade accessory pathway effective refractory peri od after lidocaine but a decrease was just as likely and there was no way of predicting a favorable response

Lidocaine did not significantly increase the mean anterograde conduction time across the AV node or the accessory pathway during sinus rhythm Accordingly it is not likely to decrease the rate of the re-entry tachycardia by this mechanism

Retrograde VA conduction We have previous ly found [1] and it is again in evidence in these patients that the atrial pacing technique overes timates the anterograde AV node effective refrac tory period as compared to the atrial extrastimu lus technique but that no such disparity exists in the case of the determination of the anterograde accessory pathway effective refractory period We attribute the disparity in the former case to the parasympathetic effects of rapid atrial pacing [5] which increase the AV node but not the accesso ry pathway effective refractory period [3] We feel that these considerations also apply in the reverse direction with ventricular pacing In this study in the determination of the VA effective refracto ry period there was excellent linear correlation between the techniques of ventricular pacing and extrastimulation and the linear regression equa tion fell close to the line of identity This suggests that it was in fact the retrograde accessory pathway effective refractory period that was determined as opposed to the retrograde AV node effective refractory period Lidocaine did not sig nificantly increase the mean retrograde accessory pathway effective refractory period as deter mined by ventricular pacing or extrastimulation Accordingly it is not likely to terminate re entry AV node accessory pathway tachycardia by this mechanism

Ruskin and co workers reported the effects of intravenous lidocaine 1 mg/kg as a bolus and 4 mg/minute by infusion on retrograde VA conduction in patients without the WPW syndrome As determined by the ventricular extrastimulus technique the mean retrograde His Purkinje system effective refractory period in four patients significantly decreased by ≥ 13% after lidocaine from 324 ± 20 msec to 281 ± 31 msec ($p < 0.005$) There were variable effects on the retrograde AV node effective refractory period in 11 patients Lidocaine would appear unlikely to terminate re entry accessory pathway AV node tachycardia by this mechanism

Lidocaine did not significantly increase the minimum retrograde accessory pathway conduc tion time during ventricular pacing at the slowest rates with 1 1 VA conduction There was a signif icant increase in the maximum retrograde acces sory pathway conduction time during ventricular pacing at maximum rates with 1 1 VA conduc tion suggesting that lidocaine may prolong the retrograde accessory pathway conduction time in re entry AV node accessory pathway tachycar dia and so decrease its rate Nevertheless such an effect was not manifest in the six patients who developed this tachycardia in the control state and after lidocaine where there was no significant change in the retrograde accessory pathway con duction time

Atrial and ventricular muscle refractoriness Lidocaine significantly decreased the mean atrial muscle effective refractory period with no signif icant change in the mean ventricular muscle effective refractory period Accordingly it is not likely to terminate the re-entry tachycardias by this mechanism A decrease in the atrial muscle effective refractory period may in fact facilitate the development or continuation of atrial fibrilla tion

Tachycardia initiation

Incidence and rate of tachycardia As intrave nous lidocaine had minimal or no effect on the effective refractory periods of the components of the re entry circuit in either direction it was not surprising that re entry tachycardia was initiated during electrophysiologic study in a similar num ber of patients in the control state and after lidocaine Furthermore as it had minimal or no effect on the conduction time across the compo nents of the re-entry circuit in either direction it was not surprising that there was no significant change in the rates of the tachycardias ini tiated

No specific attempt was made to initiate atrial

fibrillation by atrial pacing at very rapid rates During the course of the routine studies however atrial fibrillation occurred in three patients in the control state and in one of these after lidocaine In this patient the shortest RR interval of the ventricular response was minimally increased The shortest RR interval of the ventricular response correlates with the anterograde accessory pathway effective refractory period [35, 36] and in the two remaining patients the anterograde accessory pathway effective refractory period as determined by the atrial extrastimulus technique decreased by 4% and 20% Accordingly should atrial fibrillation have occurred after lidocaine in these two patients there would have been no increase and perhaps even a decrease in the shortest RR interval of the ventricular response

Tachycardia zone The initiation of re entry tachycardia by atrial extrasystoles may be expected to be less likely when the range of coupling intervals of atrial extrastimuli that initiate re entry tachycardia is found to be small Lidocaine did not significantly decrease the duration of this tachycardia zone If the outer limit of the tachycardia zone is decreased an atrial extra systole with a coupling interval at this outer limit will no longer initiate re entry tachycardia Lidocaine was successful in significantly reducing this tachycardia zone outer limit but only by 5%

Anterograde accessory pathway AV node effective refractory period difference When the anterograde accessory pathway effective refractory period is relatively great and the anterograde AV node effective refractory period is relatively small there is strong likelihood of an atrial extrasystole finding the accessory pathway refractory and the AV node available for conduction and therefore for the initial event of the re entry AV node accessory pathway circuit to occur Completion of this circuit however requires that retrograde accessory pathway conduction be intact and if in any way the retrograde effective refractory period of the accessory pathway parallels the anterograde effective refractory period such conduction will not occur Theoretically therefore it appears that there is an optimal accessory pathway AV node effective refractory period difference for initiation of re entry tachycardia by atrial extrasystoles when both the anterograde and retrograde limbs of the re entry circuit are considered together Such a relationship has already been reported [37] and appeared to be present in our cases The anterograde accessory pathway AV node effective refractory period difference was as far removed from this optimal value for tachycardia initiation in both the control state and after lidocaine Thus tachycardia initiation by atrial extrasystoles was just as likely after lidocaine as before

Clinical implications A number of aspects of the WPW syndrome were not able to be assessed by these studies These include any possible effects of intravenous lidocaine on the atrial or ventricular muscle in such a way as to prevent the extrasystoles which initiate the other arrhythmias Any such action however is not of relevance in the assessment of intravenous lidocaine as acute therapy for tachycardia that is already present Any possible effect of intravenous lidocaine on the atrial or ventricular muscle in such a way as to terminate atrial fibrillation or flutter or ventricular fibrillation likewise was not studied The significant decrease in the mean atrial muscle effective refractory period however may be expected to maintain rather than terminate atrial fibrillation

As intravenous lidocaine 1 mg/kg did not significantly depress conduction in either direction in any part of the re-entry circuit studied or alter features related to tachycardia initiation intravenous bolus administration of lidocaine is most unlikely except in isolated unpredictable cases to terminate or decrease the rate of the re entry tachycardias or to decrease the rate of the ventricular response in atrial fibrillation in patients with WPW syndrome Nevertheless larger doses than routinely used may produce transient bypass blockade

Summary

Twelve patients with the Wolff Parkinson White syndrome underwent electrophysiologic study before and after the bolus intravenous administration of lidocaine 1 mg/kg There was no significant increase in the effective refractory period of the anterograde AV node pathway the anterograde or retrograde accessory pathway or the atrial or ventricular muscle intravenous bolus administration of lidocaine is unlikely to terminate the re entry tachycardias or decrease the rate of the ventricular response in atrial fibrillation in the WPW syndrome There was no significant increase in the anterograde or retrograde AV conduction times bolus

of lidocaine is unlikely to decrease the rates of the re entry tachycardias In addition lidocaine failed to alter significantly features related to tachycardia initiation Except in isolated unpredictable cases intravenous bolus administration of lidocaine is not likely to be of benefit in the supraventricular tachyarrhythmias of the WPW syndrome

Rheumatic mitral stenosis cross-sectional echocardiographic analysis

Masahito Naito M D

Whereas M mode echocardiography proved valuable in recognizing the presence of rheumatic mitral valvular disease[1-3] its limitations in assessing the severity of the process and predicting the hemodynamic findings are well recognized[4] In contrast cross sectional echocardiography images the mitral valve apparatus from several tomographic views[5-11] and allows an assessment of mitral valve orifice size The use of the short axis view has been applied extensively to estimate the mitral valve orifice size with excellent correlation with hemodynamic data[5-13] More recently the technical difficulties in imaging the actual mitral orifice using this view have been recognized[14-16] The longitudinal left ventricular cross sectional echocardiographic view has been primarily used to recognize rheumatic mitral valvular involvement However its role in predicting the segmental anatomy and the severity of stenosis has not been fully explored The purpose of this study was to assess the specific role of the longitudinal left ventricular view in predicting the severity of rheumatic mitral stenosis and to define the spectrum of rheumatic stenosis of the mitral valvular apparatus

Materials and methods

The control population of 22 normal individuals (mean age 51 ± 10 years 55% female) identified by catheterization were selected to determine the normal mitral valve morphology and leaflet motion Twenty one patients with rheumatic mitral stenosis with no or with mild mitral regurgitation and having both hemodynamic and cross sectional echocardiographic studies within a four week period constituted the study population Their mean age was 61 ± 12 years with 76% females

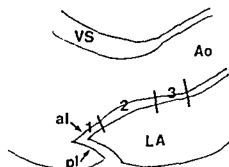

Fig 1 A schematic of the left ventricular longitudinal cross-sectional echocardiographic view demonstrating the ventricular septum *(VS)* aorta *(Ao)* left atrium *(LA)* and the anterior *(al)* and posterior *(pl)* mitral valve leaflets The anterior leaflet was divided into its tip *(1)* body *(2)* and base *(3)*

Cross sectional echocardiographic views were obtained by the methods outlined by Kisslo and associates[5] and by Silverman and co workers[7]

All cross sectional echocardiographic studies were obtained using a wide angle 84 degree commercially available phased array system (Varian V 3000) with a transducer containing 32 mounted piezoelectric crystals with a diameter of 1 3 × 1.2 inches at the skin level All studies were recorded on video tape (Sanyo) and were later reviewed in real time slow motion and frame by frame analysis Individual frame selection for figures were

photographed using a Polaroid camera The quality of these still frame images was significantly graded since only one half of the line density was present during the still framing M mode echocardiographic studies were obtained using a Smith Kline Echoline 20A with a 2 25 MHz transducer Left ventricular longitudinal and short axis views of the mitral valve were obtained using the conventional approach[1] The left ventricular longitudinal view was considered adequate when both mitral leaflets were visualized and the continuity of the anterior mitral leaflet with posterior aortic root and the interventricular septum with anterior aortic root were preserved The anterior mitral leaflet was analyzed in all 22 control individuals to define the normal range of mitral valvular motion in diastole Subsequently the mobility of the anterior mitral leaflet in diastole in the study group could be analyzed The anterior mitral leaflet was arbitrarily divided into three portions tip body and base The tip was defined as the leading edge of the anterior mitral leaflet The base of the leaflet was considered that portion of the leaflet near and at its attachment to the annulus The body of the leaflet was defined as that part between the tip and the base (Fig 1) The short axis view involved multiple tomographic sections starting at the level of the aortic valve and progressing downwards to the level of the mitral valve and then to the papillary muscles and apex The short axis view of the mitral valve orifice size was considered adequate only when the multiple tomographic views could be identified in succession and the mitral orifice size could be confidently assessed at the tip of the valve rather than a skewed view off of the true orifice (Fig 2) Gain settings were carefully adjusted as previously recommended The apical four chamber view was considered adequate when the atrioventricular valves and all four chambers were well visualized

All cross sectional echocardiographic studies were analyzed by two independent observers

The mobility of the anterior mitral leaflet was considered normal (as in controls) when the leaflet moved freely and its tip approximated the interventricular septum during diastole In the study group the tip of the leaflet demonstrated restricted motion due to commissural fusion producing a convex appearance towards the interventricular septum during diastole This doming

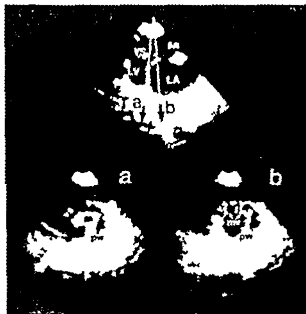

Fig 2 The top cross sectional echocardiogram reveals a left ventricular longitudinal view demonstrating the ventricular septum ( ) left ventricular cavity (LV) aorta (Ao) and left atrium (LA) The two superimposed white lines (a b) show the planes in which the short axis views labeled *a* and *b*" (below) were derived The short axis view labeled *a* depicts the mitral valve orifice at the mitral valve tip whereas the short axis view labeled *b* depicts the apparent mitral valve (mv) orifice size when the echocardiographic beam was skewed off of the mitral valve tip View a represents the actual mitral valve orifice area in this patient with mitral stenosis whereas a normal mitral valve orifice area would have been predicted if the estimation was made using view b which was obtained off of the tip of the mitral valve *pw* = posterior left ventricular wall

effect was estimated as severe (Fig 3A) if the convexity of the leaflet was striking and collided with the interventricular septum in diastole and was considered mild to moderate (Fig 3B) if the convexity of the anterior leaflet did not approximate the septum

End systolic frames were analyzed for the presence of mitral valve prolapse pattern namely a leaflet position beyond the mitral ring toward the left atrium at end systole

Severity of mitral stenosis was defined using hemodynamic findings Mitral valve orifice size was measured using Gorlin's formula Severe mitral stenosis was considered present when valve orifice size was less than 1 cm moderate between 1 and 1 5 cm and mild when more than 1 5 cm Left ventriculography was performed in the right anterior oblique view and the mitral valve was analyzed for any systolic prolapse in this view using the criteria of Cohen and associates[1]

Fig 3 The left ventricular longitudinal cross sectional echocardiographic view in *panel A* represents severe doming of the anterior mitral valve leaflet *(small white arrow)* The ventricular septum *(VS)* aorta *(Ao)* and left atrium *(LA)* are also shown *Panel B* demonstrates mild to moderate anterior mitral valve leaflet doming

Table I Correlation of the pattern of anterior mitral leaflet motion and severity of mitral stenosis

Pattern of anterior mitral leaflet motion by cross sectional longitudinal view		*Severity based on catheterization findings*		
		Mild	*Moderate*	*Severe*
Pattern A (N = 8)	Mild moderate doming (N = 2)	1	1	0
	Severe doming (N = 6)	2	2	2
Pattern B (N = 8)		0	1	7
Pattern C (N = 5)		0	0	5

Results

I Patterns of anterior mitral leaflet motion in diastole The anterior mitral leaflet could be adequately analyzed in all 21 patients with mitral stenosis Three patterns of leaflet motion were identified (Table I and Fig 4)

Pattern A Restricted motion of the leaflet s tip with doming of the whole leaflet was seen in eight patients Mild to moderate doming was noted in two of eight and severe doming was noted in six of eight Hemodynamic data identifying severe mitral stenosis were noted in only two of eight patients all of whom had severe diastolic doming of the anterior leaflet

Pattern B Restricted motion of the leaflet s tip and body with mild doming of the basal portion of the leaflet was seen in eight patients Fig 4 demonstrates this pattern, showing that the base of the leaflet is moving during the cardiac cycle while the tip and body have restricted motion Hemodynamically severe mitral stenosis was present in seven of these eight patients

Pattern C Restricted motion of the entire leaflet was seen in 5 patients all of whom had hemodynamically severe mitral stenosis Fig 4 shows an example of this pattern of severely restricted leaflet motion during systole and diastole

Thus the pattern of echocardiographic longitudinal view of the anterior leaflet motion correlated well with the hemodynamic severity of the mitral stenosis However a close correlation was not always observed in Pattern A (Fig 5)

II Extent of thickening of the anterior mitral leaflet Table II details the extent of thickening of the anterior mitral leaflet and the correlation with the degree of hemodynamic severity Five patients had no thickening of the anterior mitral leaflet while three showed thickening involving primarily the tip ten involving the tip and body and three involving the entire leaflet Patients with valvular thickening were on the average a decade older than those without thickening (Table II) The extent of thickening correlated with the severity of mitral stenosis (Table II) Thus the spread of thickening of the mitral anterior leaflet appeared to extend from tip and body towards the base When the leaflet was not thickened or only thickened at its tip the frequency of severe mitral stenosis was less than if the leaflet s body or the entire leaflet was thickened

Fig 4 These three left ventricular longitudinal cross sectional echocardiographic views were obtained from three different patients with mitral stenosis, and show the observed patterns of anterior mitral valve leaflet motion *Panel A* demonstrates doming of the anterior mitral valve leaflet *(white arrow)* with leaflet thickening isolated to the tip *Panel B* shows thickening primarily of the tip and body with relative sparing of the base of the mitral valve leaflet *(single white arrow)* *Panel C* demonstrates little anterior mitral valve leaflet motion with severe thickening of the tip body and base *Ao* = aorta *LV* = left ventricle *LA* = left atrium and *IVS* = ventricular septum

III Patterns of anterior mitral leaflet in systole Mitral valve prolapse pattern was noted in three of eight patients with Pattern A leaflet motion All three patients showed severe doming of the anterior mitral leaflet (Fig 6) and two of these three had hemodynamic evidence of severe mitral stenosis The posterior mitral leaflet was not prolapsed in any of these three patients nor did left ventriculography reveal prolapse in any patient Mitral valve prolapsing motion can be seen with rheumatic mitral stenosis (Fig 6) but appears to require a pliable anterior leaflet with severe commissural fusion and doming The presence of mitral valve prolapse pattern by cross sectional echocardiography suggested hemodynamically severe mitral stenosis The lack of posterior leaflet prolapse (Fig 6) suggested that the anterior leaflet prolapse is unrelated to the floppy valve syndrome but probably was a systolic rebound phenomenon of the markedly domed leaflet motion in diastole

Discussion

The limitations of M mode echocardiography in assessing the severity of mitral stenosis are recognized The recent introduction of cross sectional echocardiography has enhanced the ability to estimate the severity of the rheumatic process and can actually image the true orifice size of the mitral valve Henry and associates were the first to document an excellent correlation between the mitral valve area as estimated by hemodynamic data and short axis cross sectional echocardiographic imaging of the mitral orifice size However the following potential limitations to this technique are varying orifice size due to different gain settings cross sectional short axis view of the mitral valve skewed from the true orifice inability to assess subvalvular contribution due to valvular obstruction and lack of standardization of the measurement of the orifice area

The value of the longitudinal view obtained by cross sectional echocardiography has not been fully explored as a means to assess the severity of mitral stenosis Since the entire length of the mitral leaflet is visualized by this view different features of leaflet motion and thickening may reflect different hemodynamic alterations In this study we have attempted to define the spectrum of cross sectional echocardiographic findings of

Table II Extent of thickening of the anterior mitral leaflet in mitral stenosis

Number of patients	*Mean age (yrs SD)*	*Site of thickening*			*Catheterization proven severe MS*
		Tip	*Body*	*Base*	
5	5[illegible] ± 15	–	–	–	1/5
3	66 ± 15	+	–	–	1/3
10	62 ± 10	+	+	–	9/10
3	63 ± 3	+	+	+	3/3

Symbol – = no thickening + = thickening MS = mitral stenosis

Fig 5 A comparison of the left ventricular longitudinal views from two patients *(top panels)* with the short axis tomographic views *(bottom panels)* are shown Patient A demonstrated severe doming of the anterior mitral valve leaflet comparable to the degree of doming seen in patient B *(upper right hand panel)* The short axis view of the mitral valve orifice in each of these patients taken at the tip of the mitral valve revealed that although patients A and B had similar severe doming of the anterior mitral valve leaflet on the longitudinal view their mitral valve orifice areas were substantially different Patient A had a 1 1 cm and patient B had a 2 2 m mitral valve orifice area VS = ventricular septum PW = posterior left ventricular wall LA = left atrium Ao = aorta LV = left ventricle

the rheumatic mitral valvular involvement using this view

The anterior mitral leaflet motion pattern as [illegible] the longitudinal cross sectional echocardiographic view was useful in estimating the [illegible] of mitral stenosis When [illegible] was present there was loss of [illegible] tip of the anterior mitral leaflet [illegible] of the leaflet was still pliable [illegible] during diastole showing a [illegible] the interventricular septum [illegible] doming was dependent on two fact[illegible] the pliability of the mitral anterior leaflet a[illegible] extent of commissural fusion Thus with [illegible] ural fusion there was less leaflet dom[illegible] the hemodynamic severity of the stenosis [illegible] also less In contrast anterior mitral leaflet [illegible] showing severe doming correlated more [illegible] with severe mitral stenosis especially when the leaflet abutted against the interventricular septum Severe anterior leaflet doming by the longitudinal view did not always predict however the severity of mitral stenosis (Fig 5)

When the extent of thickening of the anterior mitral leaflet was analyzed it was evident that thickening tended to occur in older patients that the tip of the leaflet was the site of the earliest thickening and that the thickening tended to spread from tip towards the base Heavily thickened leaflets with basilar involvement tended to have mitral annular calcification The extent of thickening of the anterior mitral leaflet predicted the severity of mitral stenosis especially when the entire leaflet was thickened and no doming motion was seen

The occurrence of mitral valve prolapse in the presence of mitral stenosis has been previously observed [21] Nichol and colleagues found that 60% of their patients with mitral stenosis did show a systolic prolapsing pattern of the anterior mitral leaflet Others have found that mitral valve prolapse in mitral stenosis was uncommon and that the presence of both entities was merely the coexistence of two separate disease entities Our study is in support of the findings of Nichol and associates as we encountered systolic mitral leaflet prolapse in 30% of our patients with Pattern A which was correlated with the severity of leaflet doming and the degree of stenosis This suggested that the prolapse motion as seen in patients with a pliable anterior mitral leaflet occurs when the tip is restricted in motion due to commissural fusion and the body prolapses in systole as a rebound phenomenon of the markedly domed leaflet in diastole The lack of posterior mitral leaflet prolapse in these patients by echocardiography and left ventriculography suggested further that this prolapsing pattern is unrelated to the floppy valve syndrome

In conclusion the anterior mitral leaflet motion pattern on longitudinal cross sectional echocardiography may help predict the hemodynamic severity of mitral stenosis The thickening of the mitral leaflet in rheumatic disease appears to spread from leaflet tip to base and appears to involve the annulus only when the entire leaflet is thickened Mitral valve prolapse appears in patients with rheumatic mitral stenosis when the anterior leaflet is pliable and severely domed and is probably a rebound phenomenon in systole of the diastolic domed leaflet

Fig 6 Diastolic *(Diast)* and systolic *(Syst)* left ventricular longitudinal cross sectional echocardiographic views are presented from a single patient with mitral stenosis. The diastolic view demonstrates severe doming of the anterior mitral valve leaflet *(heavy white arrow)* which in systole becomes mitral valve prolapse *(small white arrow)* as a rebound phenomenon The posterior mitral valve leaflet is not prolapsed AO = aorta LA = aorta LA = left atrium VS = ventricular septum

Summary

Twenty one patients with rheumatic mitral stenosis diagnosed by both M mode echocardiography and hemodynamic findings were subjected to detailed cross sectional echocardiographic studies The age of the patients ranged from 27 to 79 years with 76% females Left ventricular longitudinal short axis and apical four chamber cross sectional echocardiographic views were obtained in each patient Three predominant patterns of anterior mitral leaflet motion on left ventricular longitudinal view were observed and correlated with the severity of mitral stenosis Pattern A (eight patients) with diastolic leaflet doming and restricted leaflet tip motion Pattern B (eight patients) with restricted tip and body leaflet motion and Pattern C (five patients) with the entire leaflet motion restricted Mitral valve prolapse as a rebound phenomenon was observed in three patients who had marked leaflet doming in Pattern A and two had severe obstruction The longitudinal cross sectional echocardiography was superior to the apical view in assessing the diastolic doming motion of the anterior mitral leaflet Thus longitudinal cross sectional echocardiographic analysis of the pliability and degree of doming of the anterior mitral leaflet is valuable in estimating the severity of mitral stenosis

Pathology of the heart in acromegaly: anatomic findings in 27 autopsied patients

J T Lie MD FACC
Stanley J Grossman
Rochester Minn

As a disease entity acromegaly was first described by Marie in 1886.[1] Cardiac enlargement and congestive heart failure were added to the symptom complex of acromegaly by Huchard in 1895 and by Fournier in 1896. Although cardiomegaly is a common finding in acromegaly its pathogenesis remains obscure after numerous studies and much scrutiny by various investigators in the last 50 years. The proposed etiologic factors of cardiac enlargement in acromegaly include hypertension coronary artery disease valvular heart disease compensatory hypertrophy secondary to increased work load induced by generalized splanchnomegaly and somatomegaly and direct humoral effects of the growth hormone. A specific entity of heart muscle disease in acromegaly (acromegalic cardiomyopathy) has also been suggested by some investigators. Postmortem findings of the heart in acromegaly are surprisingly scarce since the autopsy information was available in only a fraction of patients in most published large series of cases. In this report we review the cardiac pathology of 27 autopsy cases of acromegaly seen in a single institution over a 60 year period and compare our morphologic findings with those described in the literature.

Patients and methods

We reviewed a total of 41 autopsy cases of acromegaly culled from the Mayo Clinic autopsy records of 1919 to 1978 but only 27 cases with adequate clinical data and complete postmortem examination were included in this study comprising 16 males and 11 females. The mean age of the 27 patients at death was 50 years (range = 13 to 83 years). All but four patients died before 1960. The diagnosis of acromegaly was almost exclusively clinical because radioimmunoassay of plasma growth hormone is a relatively recent procedure.

All 27 patients had the characteristic acromegalic appearance including broad hands feet and digits which had increased in size with progression of the disease and often required larger gloves shoes and rings. Prominent jaw coarse facial features visual disturbances (especially bitemporal hemianopia) and persistent headache were also common clinical findings.

The gross specimens and histologic sections of the hearts of all 27 patients were available for review. *Significant coronary atherosclerosis* was defined as one or more vessels with 75% or greater cross sectional area luminal narrowing. *Significant aortic atherosclerosis* was defined as the abdominal aorta showing 50% or greater surface area involvement by atherosclerosis. The patient's organ weights were compared with the expected weights of organs according to the body weight or the body height. Expressing the expected organ weight as 100% the patient's organ weights were calculated as a percentage of the expected weights by the formula Actual Weight/Expected Weight × 100%. All existing and newly cut additional histologic sections of the hearts were evaluated with no prior knowledge of the heart size or the patient's clinical data. Histological diagnosis of myocardial hypertrophy was made independently of whether or not the heart weight was above the expected weight.

Results

We assigned the 27 autopsy cases arbitrarily into two groups according to the duration of the disease. Group I comprised 11 patients who died within 10 years of clinical onset of acromegaly. Group II comprised 16 patients who died 10 or more years after the onset of acromegaly. The major clinical and pathologic findings are summarized in Table I.

Cause of death. Of the group I patients, nine had hypophysectomy and one had thyroidectomy; all of these 10 patients died in the first postoperative week from surgical complications. The remaining and the sole nonsurgical group I patient died of carcinoma of the stomach. Only two of the 11 (18.2%) group I patients had organic heart disease clinically: one had mitral valve disease and congestive heart failure (Case no. 7) and the other had aortic regurgitation and congestive heart failure (Case no. 9). The cause of death of group II patients was more varied (Table I): five from surgical complications (two hypophysectomy, two thyroidectomy, and one vocal cord polypectomy), three from cardiac failure, two from stroke, two from pulmonary emboli, one each from pyelonephritis, hydrocephalus, glioblastoma, and carcinoma of the lung. Although cardiac failure was the cause of death of only three of the 16 group II patients, seven other patients (a total of 10 or 37% of the total series of 27) had clinical evidence of congestive heart failure (Table I).

Organ weights. Compared with the expected organ weights according to the individual's body weight and body height,[3] the vast majority of both group I and group II patients had splanchnomegaly, including increased heart size: hepatomegaly 93%, splenomegaly 93%, renomegaly 81%, and cardiomegaly 81%. Only nine patients (33%) in the entire series had heart weights exceeding 500 g, all but one in group II (Table I). The largest heart in the series, 1,300 g, was 3.7 times the expected weight (Fig. 1). The increase in heart size appeared to be related to the duration of the disease (Fig. 2) and unrelated to the presence of hypertension or coronary artery disease. The proportions of patients with heart weights greater than the expected weights in group I and group II were 63.6% (seven of 11) and 93.8% (15 of 16), respectively. The difference was statistically significant ($p < 0.01$) according to the rank sum test. Cardiomegaly was disproportionate to hepatomegaly, splenomegaly, and renomegaly in 33%, 26%, and 30%, respectively (Figs. 3, 4, and 5). None of the hearts showed asymmetric septal hypertrophy.

Cardiac abnormalities. Clinical hypertension, defined as blood pressure recordings of 160/95 mm Hg or higher, was present in three (27%) of group I and nine (56%) of group II patients (Table I). Eleven of the 12 (91%) hypertensive patients had cardiomegaly. However, cardiomegaly was also common among the nonhypertensive acromegaly patients, being present in 73% (11 of 15) of cases. Four of the group I and none of the group II patients were diabetic. Significant coronary artery disease was present in three of 27 cases

Fig 1 A normal si ed 3,0 g heart *(on the left)* is dwarfed by the giant 1 300 g acromegalic heart *(on the right)*

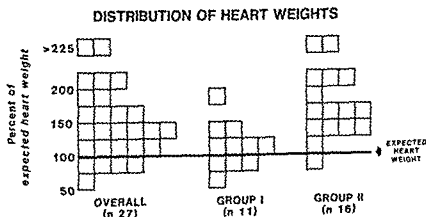

Fig 2 Histograms showing distribution of heart weight in acromegalic patients Expected heart weight according patient s body weight and body length is expressed as 100 percent Group I patients died within 10 year of lini al onset of acromegaly and group II patients died 10 or more years after the onset of acromegaly

(11(the ages of these three patients were 57 73 and 81 yea Gro s evidence of old myocardial infarction was found in four of 27 cases (15%) ag in each of these four patients was 57 years old or older Significant atherosclerosis of the abdominal a t t was f und in s of 27 cases (21%) five of the e i pat e s were 7 years old or older Aortic and mitral valvular heart disease was present in e t 27 cases (19%) two had aortic regurgitation tw had mitral stenosis and regurgitation (n n historically or morphologically rheumatic i fu tic in origin) and one had calcific aortic stenosis and regurgitation secondary to old h d t bacterial endocarditis

Review of m r h topathology generally showed varying d of myocardial hypertrophy and intersti l fibro s (Fig 6) Myocardial hypertrophy was present to some extent in 25 (93%) of 27 cases and involved the myocardium of both ventricles Focal myocardial fiber disarray (Fig 7) was observed in five cases (19%) Interstitial fibrosis was seen in 23 (85%) of 27 cases almost invariably accompanying myocardial hypertrophy Other histologic findings which appeared frequently were interstitial lymphomononuclear infiltrate and small vessel disease The myocardium in 16 of 27 cases (59%) showed a continuum of changes from mild nonspecific interstitial cellular infiltration to true myocarditis Myocarditis which may be focal or diffuse (Fig 8) was observed in seven hearts (26%) Six of 27 patients (22%) had significant wall thickening of the small intramural branches of the coronary arteries unrelated to myocardial scar tissue (Fig 9) Four

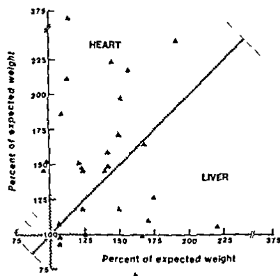

Fig 3 Comparison of the corresponding actual heart weight *(ordinate)* and actual liver weight *(ab ci a)* in acromegalic patients Expected organ weight according to patient s body weight and body height is expressed as 100 percent *The shaded area* represents ±25% of the expected (100%) organ weights *Points outside the shaded area* are regarded as disproportionate organomegaly heart to the left liver to the right of the diagonal solid line

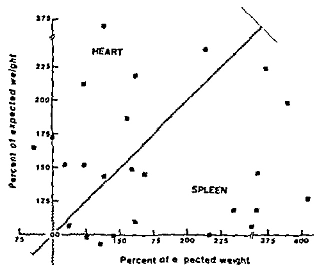

Fig 4 Comparison of the corresponding actual heart weight *(rdinate)* and actual pleen weight *(ab ci sa)* in acromegalic patients Expected organ weight according to patient s body wei ht and body height i expressed as 100 percent *The haded area* represents ±25% of the expected (100%) organ wei hts *P int ut i le the shade l area* are regarded as disproportionate organomegaly heart to the left pleen to the ri ht of the diagonal solid line

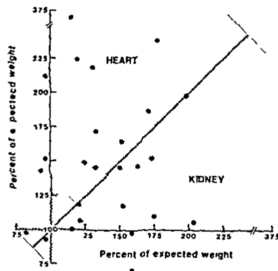

Fig 5 Comparison of the corresponding actual heart weight *(ordinate)* and actual kidneys weight *(ab ci a)* in acromegalic patients Expected organ weight according to patient s body weight and body height is expressed as 100 percent *The haded area* represents ±25% of the expected (100%) organ weights *Points outside the shaded area* are regarded as disproportionate organomegaly heart to the left kidneys to the right of the diagonal solid line

of the six patients who had small vessel disease of the heart were clinically hypertensive and one of the four also had diabetes mellitus The prevalence of the various pathologic changes of the heart in group I and group II patients are compared in Table II

An *additional autopsy finding* that occurred commonly was thyroid enlargement Only five of the 23 thyroids examined at autopsy were normal the remaining 18 (78%) were adenomatous (15 cases) or showed Hashimoto thyroiditis (three cases) It was noted that four of the 27 patients in this series had undergone thyroidectomy for hyperthyroidism

Discussion

Cardiac failure as a major cause of morbidity and mortality in acromegaly has been repeatedly emphasized in the past However most of the previously published studies of cardiovascular disorders in acromegaly are either purely clinical ly oriented or have included only a small number of autopsied patients There are also reports of large series that do not deal with cardiac findings in any detail The results of a recent prospective study of 57 patients by McGuffin and associates are at variance with many of the conclusions of the earlier studies notably the lack of correlation between hypertension cardiac disease and the growth hormone concentration in acromegaly Unfortunately only eight autopsied

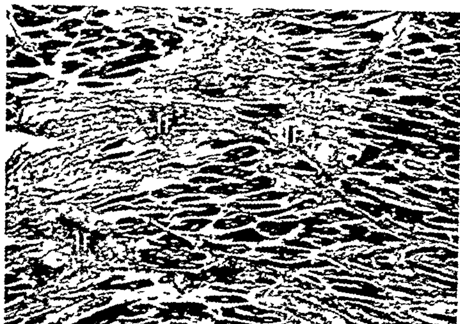

Fig 6 Typical histologic appearance of acromegalic heart showing interstitial fibrosis *(IF)* and hypertrophied myocardial fibers (Mallory Heidenhain stain original magnification ×1?0)

Fig 7 H [illegible] appearance of focal myocardial fiber disarray in acromegalic heart (Hematoxylin-eosin original [illegible])

cases were [illegible] in the report by McGuffin and [illegible]

Autopsy Series of Acromegaly Acromegaly is sufficiently [illegible] that the number of autopsy cases fr[illegible] single institution is necessarily limited In [illegible] survey of case records of acromegaly [illegible] different medical centers Wright and co-workers were able to identify a total of 194 cas[illegible] which there were 55 deaths but the postmortem reports were available [illegible] only 26 patients The 27 patients included in o[illegible] series were selected (on the basis of availability [illegible] tissue specimens for review) from a total of 4[illegible] autopsy cases in the Mayo autopsy record [illegible] 1919 to 78 In this 60 year period the to[illegible] number of autopsies performed at Mayo wa[illegible] 45 767 representing an autopsy incidence [illegible] acromegaly of 1 in 1 116

Fig 8 A Histologic appearance of myocarditis in acromegalic heart B The boxed area in A is seen at higher magnification showing individual myocyte necrosis and lymphomononuclear cell infiltrate (Hematoxylin-eosin A original magnification ×48 B original magnification ×300)

Review of our autopsy cases of acromegaly bears many disadvantages that are inherent to all retrospective studies but the potential benefits of understanding the pathogenesis of a disease process with the aid of detailed postmortem findings should be equally obvious Because all but four deaths in our series occurred before 1960 we lack data to comment on the significance of growth hormone concentration in relation to cardiovascular disorders of acromegaly This aspect has been fully discussed by McGuffin and associates The separation of our 27 autopsy cases into two groups though arbitrary (based on the known duration of acromegaly from diagnosis to death) makes interesting comparison with reference to the mortality cause of death and cardiac abnormalities (Table II)

Mortality and cause of death Patients with acromegaly are known to have a reduced life expectancy In the collective series of 194 cases reviewed by Wright and colleagues[11] 26% of deaths occurred before the age of 50 years and 64% by the age of 60 years Even higher figures were noted in an earlier study of 100 cases by

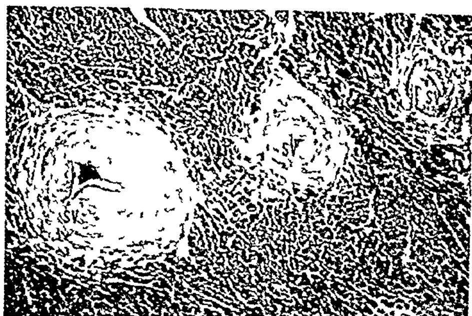

Fig 9 Histologic appearance of proliferative wall thickening of small intramural vessels (SV) in acromegalic heart (Hematoxylin eosin original magnification ×49)

Table II Cardiac pathology in acromegaly (autopsy series)

Group	Group I (n = 11)	Group II (n = 16)	Total (n = 27)
Sex ratio (M/F)	3/8	13/3	16/11
Mean age (yr) at death	39.5	57.9	50
Hypertension (≥ 160/95 mm Hg)	3 (27%)	9 (56%)	12 (44%)
Diabetes mellitus	4 (36%)	0	4 (15%)
Clinical heart failure	2 (18%)	8 (50%)	10 (3[illegible]%)
Cardiomegaly	7 (64%)	15 (94%)	22 (81%)
mean heart weight (g)	349	618	496
Coronary artery disease	0	3 (19%)	3 (11%)
Aortic atherosclerosis	0	6 (38%)	6 (22%)
Valvular heart disease	2 (18%)	3 (19%)	5 (19%)
Myocardial hypertrophy	10 (91%)	15 (94%)	25 (93%)
Interstitial fibrosis	8 (73%)	15 (94%)	23 (85%)
Cell infiltrate or myocarditis	5 (45%)	11 (69%)	16 (59%)
Small vessel disease	2 (18%)	4 (25%)	6 (22%)

[illegible] died [illegible] than 10 years of diagnosis of acromegaly Group II patients died more than 10 years after diagnosis of acromegaly
[illegible] expected weight by body weight or body length only [illegible] (36%) of [illegible] cardiomegaly cases were recognized clinically
[illegible] arteries with ≥ 75% cross sectional luminal narrowing
Abd[illegible] with ~ 50% surface area involvement by atherosclerosis
[illegible] the [illegible] with histological myocardial hypertrophy were within the normal range (i.e. no cardiomegaly)

Evans and co-workers who reported 50% of deaths before the age of 50 years and 89% by the age of 60 years. There was a heavy bias of surgical deaths in our group I patients nine of the 11 patients died before 1940 in the pre antibiotic era also at the time of the more hazardous transfrontal craniotomy for resection of pituitary tumors All seven (2[illegible] of the series) cardiovascular deaths (three cardiac failure two stroke and two pulmonary embolism) occurred in group I[illegible] patients in whom acromegaly was diagnosed fo[illegible] 11 to 39 years A greater prevalence of cardiovascular disorders among patients who had the[illegible] acromegaly longer was also noted in the prospec[illegible]tive series reported by McGuffin and asso[illegible]ciates

As has already been noted by Wright and colleagues the particular speciality of the ho[illegible]

tal may in part determine the observed causes of death in acromegaly Of the two older studies diabetic coma was the most common cause of death in a report published in 1927[4] and intracranial extension of the pituitary tumor was the commonest cause of death in another report published in 1964[7] In the survey conducted by Wright and co workers[13] increased mortality was found to be associated with hypertension and clinical diabetes but not with chemical diabetes The 26% incidence of deaths from cardiovascular disorders in our series was in close agreement with the 24% reported by Wright and colleagues[13]

Pathogenesis of cardiomegaly Organomegaly including cardiac enlargement has been so consistently identified with acromegaly that Levene and Miller[30] considered it worthwhile to report a case because the heart was normal in size Although the literature is replete with reports of acromegalic hearts in excess of 1 000 grams[4, 5, 7, 8] it is still more common to find acromegalic hearts weighing several hundred grams less than the kilogram range The mean heart weight was 486 grams in our series of 27 patients but a trend toward progressive cardiac enlargement with longer duration of acromegaly was evident The mean heart weight of our group I patients (acromegaly less than 10 years) was 348 grams whereas the mean heart weight of our group II patients (acromegaly more than 10 years) is 618 grams Of the 22 patients in whom cardiomegaly was found at autopsy only seven (36%) were recognized to have roentgenologic evidence of cardiac enlargement clinically

Disproportionate cardiomegaly (cardiac enlargement proportionately greater than enlargement of other visceral organs) has often been cited[11, 9] as a uniform finding in acromegaly This notion was unsupported by our autopsy data when cardiomegaly was compared with the enlargement of the liver spleen and kidneys in the same patient (Figs 3 4 and 5)

Premature or accelerated atherosclerosis as a cause for the cardiac hypertrophy in acromegaly was first suggested by Huchard in 1895 and an increased incidence of significant coronary and aortic atherosclerosis in acromegalic patients has been repeatedly cited since then[3] This was not substantiated by autopsy data since only 11% of cases had significant coronary artery disease and 22% of cases had significant aortic atherosclerosis (Table II) all signs were found in patients at an age when more advanced atherosclerosis would be expected normally

Valvular heart disease in association with acromegaly was seldom discussed in the past Courville and Mason[3] cited no data but stated that cardiac disease in patients with acromegaly was probably due to some etiologic factors other than valvular disease Indeed valvular disease was not uncommon (19%) in our patients and appeared to contribute little to cardiac hypertrophy in acromegaly

The importance of hypertension in cardiomegaly is highly contentious Reports of the incidence of high blood pressure in acromegaly range from 8 to 57%[7, 1, 16] The over all incidence of hypertension was 44% in our series it occurred twice as commonly in group II as in group I patients (Table II) Some authors postulate an important causal relationship between hypertension and cardiac enlargement in acromegaly[9, 1] but others disagree[1, 31] Although five of the seven largest hearts in our series were found in hypertensive subjects 11 (73%) of the 15 nonhypertensive patients also had cardiomegaly (Table I) Typically the hypertension was mild uncomplicated and responsive to drugs as previously noted by McGuffin and co workers[1]

Similarly it seemed unlikely that *diabetes* was a major etiologic factor of cardiomegaly in acromegaly only four (15%) of our 27 autopsied patients were diabetic In reviewing Harvey Cushing s patients Coggeshall and Root[6] found 26 (17%) *diabetes in 153 cases of acromegaly* The average interval between the onset of acromegaly and diabetes was 9 2 years According to the authors the clinical character of the diabetes associated with acromegaly did not show any greater variation in severity resistance to insulin and life expectancy than was seen in a large group of diabetic subjects without acromegaly

The direct effects of growth hormone on heart size remains an unsettled issue DeGrandpre and Raab[3] showed that repeated doses of growth hormone in the presence of a normal work load caused cardiac hypertrophy in rats Some authors feel this also applies to human hearts while other investigators deny it[14, 19, 1] According to McGuffin and colleagues[9] hypertension was the only abnormality that correlated with the plasma growth hormone concentration but a marked

reduction in plasma growth hormone concentration although not usually normal, did not *influence the hypertension*

Some authors[5,13,17,0] have suggested the possibility of a specific entity *acromegalic cardiomyopathy,* in which cardiomegaly is present in the absence of hypertension atherosclerosis, or severe valvular disease Indeed 33% (nine of 27) of cases in our series fell within this category (Table I) This possibility merits further consideration though the currently available evidence does not fully support it Two recently reported clinical studies[4] have shown that most acromegalic hearts function normally even when their mass is considerably enlarged and subclinical cardiac dysfunction is uncommon among asymptomatic patients with acromegaly However in an earlier study Jonas and co workers[9] reported a high incidence of subclinical cardiac muscle disease in 10 acromegalic patients on the basis of abnormal systolic time intervals

Another possibility that pituitary products other than growth hormone may be responsible for the unexplained cardiomegaly in acromegaly also warrants serious consideration Curtarelli and Ferrari[11] have recently reported an interesting case of massive cardiomegaly with heart failure in a 42 year old hyperprolactinemic woman in whom a pituitary tumor had been treated by radiotherapy five years previously Since prolactin is known to exert metabolic *growth hormone like effects in animals and in* man the authors conjecture that prolactin hypersecretion might induce or maintain cardiac disease in patients with pituitary tumors In a preliminary survey of 35 hyperprolactinemic subjects Curtarelli and Ferrari[11] have found five with raised blood pressure and four two of whom were normotensive with cardiomegaly on chest roentgenographs

Histopathology of acromegalic hearts The occurrence of myocardial hypertrophy and interstitial fibrosis in acromegalic hearts is well known[7] The heart weight of three patients with myocardial hypertrophy were within the normal range Nonspecific lymphomononuclear cell infiltrate (nine of 27 cases or 33%) true *myocarditis (seven of 27 cases or 26%)* and small vessel disease (six of 27 cases or 22%) have rarely been recognized or described previously Small vessel disease and foci of mild cellular infiltrates in the interstitium have been seen occasionally in hypertrophied hearts from a variety of causes, including acromegaly, but their etiology is unclear Nor is the etiology of myocarditis in acromegaly known Morphologically, the myocarditis in acromegaly is reminiscent of myocardial lesions observed in experimental animals *after norepinephrine infusion[34,36] and in patients* with pheochromocytoma[37] It is speculated that the myocarditis in acromegaly might be causally related to the altered homeostasis of endogenous catecholamine secretion Of interest a recent report by Van Loon[3] has shown abnormal plasma catecholamine responses to the suppressive effects of bromocriptin (a dopaminergic agonist) and luteinizing hormone releasing hormone in acromegalics Whatever the mechanism might be in the development of myocardial lesions in acromegalics myocarditis is a possible contributing factor to cardiac failure in these patients though not necessarily the cause of cardiomegaly

Conclusions Cardiomegaly was common but not inevitable, in acromegaly, being present in 81% of our series of 27 autopsy cases The enlarged heart seldom exceeded 200% (i e twice) of the expected heart weight according to the patient's body weight and body height Contrary to the prevailing view, disproportionate cardiomegaly (in comparison with hepatomegaly splenomegaly, and renomegaly) was not a uniform *finding it occurred in one fourth* to one third of our cases Cardiomegaly appeared to be related to the duration of acromegaly, and was present in both hypertensive and nonhypertensive subjects Our data did not support another common belief that premature or accelerated atherosclerosis and diabetes were causally related to acromegaly and *cardiac failure in acromegaly* The possibility that a specific acromegalic cardiomyopathy may exist cannot be discounted by the currently available evidence The significance of small vessel disease and myocarditis in acromegaly has not been discussed in earlier pathologic studies of acromegaly and warrants further probing

Summary

The morphologic characteris ... pathogen
esis of cardiac enlargement in ... remain
poorly understood partly bec ... paucity
of detailed anatomic studies ... s per

out elsewhere rheumatic fever has a truly wide spectrum of presentation and based on our observations a condition called mild rheumatic fever may indeed exist In our series we found that about one-fourth of the patients with rheumatic heart disease had presented with one or several episodes of recurring and migrating polyarthralgia with associated low grade fever one week to several months before carditis was diagnosed It would thus seem that perhaps in areas of high incidence some patients develop mild attacks of rheumatic fever which go unrecognized and subsequently develop a recurrent attack which is often looked upon as the first attack And the reason for failure to diagnose the mild attack is a simple and absolute reliance on the Jones criteria

It is perhaps advisable that until further knowledge is gained regardin the possibility of such sequences of events particularly in areas of high incidence the clinician should watch for patients with arthralgia high ASO titer and elevated erythrocyte sedimentation rate Such instances would certainly deserve closer observation regarding future streptococcal throat infection and occasionally in the presence of strong family or sibling history of rheumatic fever one may justify prophylaxis for some time Most certainly the parents of such children deserve a thorough orientation with regard to rheumatic fever Due to the rarity and non pecificity of subcutaneous nodules and *erythema marginatum* their usefulness *in the diagnosis of rheumatic fever can be questioned*. Thus, in the future a modified approach to the long honored Jones criteria may be warranted

We wish to thank Dr Aryanpur who comes to America from the rheumatic fever front line of a (ever so painfully!) developing country for his flattering and thoughtful comments The possibility that malnutrition early in life predisposes to rheumatic fever is intriguing especially since experimental studies have shown that chronic moderate protein deficiency increases susceptibility to group A streptococcal infections in mice as one of us and El Sadr noted in an earlier review more slanted toward pathogenesis Dr Aryanpur s advice that the clinician watch for patients with arthralgia high ASO and elevated ESR is well taken and so is the option of prescribing prophylaxis in some cases that do not quite fulfill the Jones criteria with pedantic completeness After all the Jones criteria are a *guide* to the clinician not a clinician And who can draw the line between a mild arthritis and a severe athralgia with any certainty? As Daniel McCarty is fond of saying (only half in jest) an arthralgia is often an arthritis minus a good physical examination

Beta blockers and running

To the Editor

In a letter to the Journal, Doctor Adrian Williams relates his experience of jogging while being on therapy with 80 mg propranolol daily for mild hypertension (Am Heart J 98 542 1979) He states that before a marathon I allow myself the luxury of stopping my treatment this seems the equivalent of a 20 pound weight loss and my performance improves by at least 20 to 30 seconds per mile"

The experience of Doctor Williams is probably shared by a number of physically active men on beta blockers and it seems important to clarify to what extent such therapy affects the physical capacity We have recently completed a study

VOLUME 100

JULY DECEMBER 1980

(Int J Sports Med in press) where the effects of 80 mg propranolol and 100 mg atenolol and placebo (double blind design) on the 2 000 m running time was measured in a group of healthy volunteers and related these results to muscle fiber composition As expected individuals with a high percentage of slow twitch fibers ran faster both times than those with a high percentage of fast twitch fibers However when on propranolol the performance was relatively more impaired in individuals with a high percentage of slow twitch fibers than in those with a high percentage of fast twitch fibers Individuals with a high percentage of slow twitch fibers took 20% to 30% longer to complete their 2 000 m running On atenolol 100 mg the same individuals needed less than 10% longer to complete the 2 000 m running Thus cardioselectivity (β selectivity) seems to be of importance to joggers

Hypertensive individuals previously accustomed to physical activity can expect a certain degree of deterioration of their performance capacity when treated with beta blockers It seems important that adequate information about these side effects of beta blockers is included in the over all information to hypertensive patients

However it also seems important to warn against unguided withdrawal of antihypertensive drug therapy

To the Editor

It is interesting to have the data of Dr Kayser and his colleagues to support my anecdotal experience with beta blockers and exercise The 20% to 30% slowing they noted in the 2 000 m time of individuals with a high percentage of slow twitch fibers (presumably those best equipped for running long distances) correlates well with this I am of course intrigued to think that cardioselective blockade might impede my training less but then the value of such "loaded" training would then be reduced

Lo—the poor Eskimo!

To the Editor

Dr Oster's Edit[illegible] [illegible] ity in a Committee Report on Diet and Coronary Heart [illegible] (AMERICAN HEART JOURNAL April 19[illegible] [illegible] attack the suggestion of the Nutrition Comm[illegible] [illegible] an Heart Association that a diet high in sat[illegible] [illegible] cholesterol is an important factor for a high incidence of coronary heart disease Dr Oster argues that to establish a causal relationship it must be shown that all population groups with a high saturated fat and cholesterol intake also exhibit a high incidence of atherosclerosis This is decidedly not the case with the French the Eskimos and the Masai, all populations *consuming diets high in saturated fats.*

The Eskimos are probably the most frequently quoted, or rather—as factual research in contrast to popular assumption has shown—misquoted example used *ad nauseam* in this controversy Most researchers found that Eskimo groups living a relatively traditional life style consumed despite their predominantly carnivore diet not more but substantially less fat than other North Americans Furthermore the fats they consumed although derived from animals were *not* highly saturated as presumed by Oster and others In fact, a much higher content of long chain polyunsaturated fatty acids than prevailing in North American diets was found in diets of Greenland Alaskan and Canadian Eskimos. Platelet lipid analysis in Greenland Eskimos reflected their high consumption of omega 3 polyunsaturated fatty acids and this results in a significantly longer bleeding time due to a reduction in platelet aggregation

These recent biochemical and physiological findings may explain earlier epidemiological observations that Eskimos were relatively free of thrombotic cardiovascular diseases but suffered from increased bleeding tendencies with undue frequency of severe postpartum hemorrhage and Sheehan's syndrome The degree of deviation from modern North American norms or the inversely related thrombotic and bleeding tendencies in various Eskimo population groups shows clear trends in geographical distribution and changes with time best explained by changes in their diet

Eskimos do therefore provide a good example *for and not against* the validity of the fourth report of the American Heart Association Committee on Nutrition and similar recommendations issued in recent years in various countries.

I hope that drawing attention to these facts will help to relieve the Eskimos from being used as *false witnesses for the* fat lobby a practice entrenched by repetition of popular myths never supported by factual research Indeed, their example provides valid ammunition *for the side advocating* dietary intervention I suspect that *the other two population* groups used in your editorial argument against the recommendations of the Nutrition Committee—namely the Masai and the French—are also not very suitable examples The Masai are subjected to frequent periods of famine and regularly have to walk long distances as nomadic cattle herders [illegible] French men drink fair amounts of wine Famine physical exertion and wine drinking all tend to elevate high density lipoproteins which may counteract the effect of low and very low density lipids and cholesterol There may be other complicating factors evident to observers more familiar with local conditions in France and East Africa than I am

To the Editor

It would indeed be presumptuous of me to enter into an argument with Dr Schaefer about the diet of the Eskimos I accept his expertise on this subject However in its imbalance the Eskimo diet does not approximate the American Heart Association Committee on Nutrition s suggested dietary proportions nor do the Eskimos have high serum cholesterol values. Eskimo summer food was found to consist of 3 protein 21% fats and 46% carbohydrates With this high protein consumption it is understandable how the name Eskimo or eater of flesh " was derived Eskimos prefer to be called Inuit (man)

The low heart attack rate of the Eskimos is ascribed to their intake of eicosapentaenoic acid (EPA) which might be partially substituted for arachidonic acid thereby reducing thrombogenesis However the diet which causes bleeding tendencies in the flesh-eating Inuit seems to have no influence on serum cholesterol. I do not think Dr Schaefer would suggest such an unbalanced diet for the North American population at large

It is disconcerting to me that Dr Schaefer falls into the common trap of alibiing commonly known findings in order to prop up the faltering diet heart cholesterol hypothesis I have studied the nutrition of the Masai and published my findings Their diet includes 60% saturated fats from curdled milk It is ludicrous to equate their lack of coronary heart disease with the walking of long distances and frequent periods of famine The lumber workers of East Finland an agrarian population expend much more of their caloric energy in pursuing their livelihood than do nomadic cattle herders They live in a lower stress situation than an urban population and still have the highest coronary heart disease rate in the world I hope that Dr Schaefer is not serious when he accepts the wine drinking habits of French men as the reason for their experiencing less coronary heart disease than similar American men with the identical risk factor constellation despite the documented high saturated fat intake of the French This naivete of wishing away findings contrary to one s favorite idea is shared by Stamler who blames the differences in coronary heart disease incidence between European and American men on the European food deprivation of World War II another alibi Even the mentors of the Framingham Study have changed their opinion about serum cholesterol "The previous position that virtually all of the lipid information pertaining to coronary heart disease resided in the serum total cholesterol must be (accordingly) modified

Self styled and chest thumping experts transpose a paucity of nutritional knowledge into an abundance of diverse and questionable advice on altering nutrition and the food supply system of the nation A brouhaha was created in May 1980 by the recommendation on fats and cholesterol in the diet by the Food and Nutrition Board of the National Academy of Sciences National Research Council The Board s action was consistent with its recommendations of 1972 However slanted nutrition research in the political arena has fostered dissension and varied and unsubstantiated recommendations Examples are (1) U S Senate Select Committee on Nutrition and Human Needs *Dietary Goals for the United States* (2) U S Department of Agriculture and the U S Department of Health Education and Welfare *Nutrition and Your Health Dietary Guidelines for Americans* and (3) the Surgeon General s report on health promotion and disease prevention *Healthy People* Each differs in its stance on cholesterol and fats, and all are out on a limb Proponents of dietary changes have not come to a meeting of the mind and stray in different directions thereby confusing the American consumer The dissonance of recommendations in the ranks of the AHA s Committee on Nutrition which was the theme of my Editorial has spread and is now to be found in most nutrition scenarios of politically inspired organization

Rupture of myocardium and mitral valve replacement

To the Editor

In their article in the January 1980 issue of the AMERICAN HEART JOURNAL Cobbs and associates have presented eight cases of rupture of the myocardium as a result of mitral valve replacement involving severance of the chordae tendineae

We have been mea uring the fiberpath angles of the myocardium in humans and other mammals for some years now and have shown conclusively that the angle change transition from epi to endocardium in the normal heart is smooth and predictable The fiberpaths obey a theorem of Clairaut which states that r cos α = a constant This translates into radius times the cosine of the angle tangential to the epicardium is a constant

The fiberpath angles at epicardium (and at endocardium) are dependent upon the shape and size of the heart and the thickness of the myocardium If the wall is thick—i.e the ratio of the in ide diameter to the outside diameter (r /r₀) in the contracted state is mall the angles are likely to be steeper at epicardium (~ −80 degrees ± 10 degrees) and at endocardium (~60 degrees ± 10 degrees) than if the ratio is large (α at epicardium ~ −60 degrees ± 10 degrees at endocardium ~40 degrees ± 15 degrees, relative to the longitudinal axis running through the left aortic valve commissure and the apex of the left ventricle) At least, that is what we have found If the epicardial fiberpaths can be seen and if the wall thickness is known a very rough estimation of the endocardial fiberpath angles can be made In fact if the epicardial angle is known and the r /r ratio is known the angles can be estimated again very roughly through the whole thickness of the myocardium by drawing a strai ht curve from say −70 degrees to 50 degrees If we divide the wall thickness into quantiles, the epicardial quantile is in t alance with the endocardial quantile in accordan e with the Clairaut theorem The quantile next inside epicardium is in balan e with the quantile next in ide endocardium and so on W h wn th perimentally It is obvious th refore that s ra f th hordae tendi neae in mitral val e repl en lea th n rdium just basal to the papill m sc r tt n at in lan e with the epicardial fiberpath at th tud h m v fiber because it is a branched structure f m king a dju tment to the pred minant fiber th th w thin the sibility of its branches If the a n nt rupture must

(As ass med zero)

and does occur Fig 3 (Case No 2) of Cobbs and associates article shows dramatically that an attempt at readjustment was made It failed Balance could not be restored The figure also shows the transition from the midwall cross-cut fibers on the right, via those cut at intermediate oblique angles, to those which the authors call plunge fibers" that we suspect are fiberpaths that had attempted to restore Clairaut balance but failed.

Leaving the chordae tendineae attached to the posterior leaflet intact preserved the Clairaut balance Ideally all chordae should be left intact but if severance is unavoidable perhaps collagen sutures longitudinally oriented from the free end of the papillary muscle would take up the load longitudinally

I thank Ms Ross and Dr Streeter for their thoughtful letter and regret not having been previously familiar with their detailed anatomical work which offers elegant theoretical ground for expecting the complication we described As they imply the structure we call the mitral loop is merely part of a complex system of epicardial to endocardial fiber paths It is a pleasure to learn that our concept of a dynamic balance of tension between epicardial and endocardial members of the loop may have mathematical validity We believe that mid ventricular disruption has been around for a long time often in latent or only partly expressed form But the advent of cardioplegia and perhaps trut trauma from the new hypothermia theses have set the stage for a fuller realization of the ul ma e pathology

Cyclophosphamide cardiomyopathy

To the Editor

The Annotation on anthracycline cardiotoxicity by Henderson and Frei very nicely summarizes both acute and chr

D

E

F

G

toxicities associated with the use of these agents The incidence of these phenomena is likely to increase with the recent approval of daunorubicin for treatment of adult nonlymphocytic leukemia by the FDA so their information is timely

In their report however Henderson and Frei state that cyclophosphamide (CTX) when used in large single doses has caused acute mild pericarditis The fact of the matter is that CTX in large doses (144 to 2 0 mg /kg) used prior to bone marrow transplantation has caused death from severe refractory myocardial failure Signs of CTX cardiomyopathy include loss of R waves and ST T wave changes on the ECG However interpretation of these findings is difficult because they are nonspecific and frequently transient The incidence of ECG changes at doses of 170 mg /kg of CTX appears to be approximately 90% Also elevation in serum myocardial enzymes (CK, SGOT and LDH) has been observed at approximately a 40% frequency with the same dose Overt congestive heart failure did not occur at this dose

When compared with anthracycline cardiomyopathy CTX s effects appear to be different CTX cardiomyopathy has an acute onset with death occurring from intractable heart failure in reported cases within 15 days of the initial dose The effects are dose-related but do not appear to be the cumulative result of long term drug administration Cardiac morphology at autopsy is characterized as hemorrhagic myocardial necrosis which may be focal with fibrin microthrombi in capillaries and interstitial fibrin deposition An exudative nonmalignant pericardial effusion is usually present in addition to pulmonary edema and ventricular hypertrophy A proposed mechanism of CTX cardiotoxicity is direct endothelial damage leading to extravasation of blood containing high concentrations of drug which subsequently produces myocardial cell damage fibrin precipitation and focal hemorrhage with development of refractory congestive heart failure Unlike anthracycline cardiotoxicity no risk factors for CTX cardiomyopathy have yet been identified

As more is learned about marrow transplantation and the aggressive nature of conditioning regimens using high doses of chemotherapeutic agents increases the frequency of many untoward effects including cardiotoxicity is also likely to increase

We agree completely with the comment made by Dr Roberts in the above letter In fact the sentence which he quotes from our article represents a typographical error in the initial submitted manuscript which was not picked up in multiple proofreadings The correct statement as concerns Applebaum and associates in the quoted reference should have been that single doses have caused acute myocarditis instead of mild pericarditis We appreciate Dr Roberts bringing this point to the attention of readers because we too feel that it is an important point

Effects of antiarrhythmics in ischemic models

To the Editor

We read with interest Levites and Anderson s paper concerning the electrophysiological effects of disopyramine during myocardial ischemia They and several other authors have shown local anesthetic antiarrhythmics to possess degrees of selective electrical depression in ischemic models As postulated by Levites and Anderson nonuniform drug distribution within myocardial tissue may be an important explanation of selective depression of ischemic tissue by antiarrhythmic drugs We would like to offer a working model regarding altered antiarrhythmic availability to the ischemic myofibril

As a result of ischemia normal myocardial substrate utilization is transformed to anaerobic glycolysis with an ensuing intracellular acidosis The magnitude of the acidosis in the extracellular space exceeds that of extracellular fluid with intracellular pH dropping below 6 0 Recent information seems to show that local anesthetic antiarrhythmic actions are dependent upon an active ionized form and their ability to gain entrance to an intracellular site of action Because local anesthetics are weak bases and considering the intracellular acidosis present in the ischemic myocardium Kupersmith and colleagues theorized a higher degree of intracellular ioniza

H

I

J

Table I

Agent	Acid/base	pKa	% ionized at pH 7.4	% ionized at pH 6.0
Quinidine	Base	8.34	90	99
Procainamide	Base	9.24	98	99
Disopyramide	Base	8.36	90	99
Lidocaine	Base	7.86	73	99

tion of the antiarrhythmic Thus the availability of active cationic antiarrhythmic to an intracellular receptor site may improve

Table I shows the pKa and percent ionized at pH 7.40 (physiologic) and pH 6.0 (ischemic intracellular space) for several local anesthetic antiarrhythmics The percentage ionized of disopyramide increases to nearly 100% in an acid media Quinidine and procainamide show similar changes with lidocaine changing most in percent ionized from physiologic to acid pH In publications investigating these antiarrhythmics it appears that the *degree* of selectivity in ischemic tissue parallels the change in percent of drug ionized expected to be available in the intracellular space

Further studies similar to Levites and Anderson's are certainly warranted to elucidate effects of antiarrhythmics in ischemic model. We believe the physicochemical properties of specific local anesthetic antiarrhythmics remain the key to understanding the concept of selective depression of ischemic tissue

Serum myoglobin as a sensitive index of myocardial infarction

To the Editor

We read with great interest the article of Tommaso Salzeider Arif and Klutz concerning CK and myoglobin in myocardial infarction We disagree however with their statement that myoglobin is an insensitive marker of myocardial necrosis in its early phase because of its lack of appearance in 50% of their patients having definite acute myocardial infarction

We have recently examined 15 patients with acute myocardial infarction seven with diaphragmatic infarction and eight with anteroseptal infarction In all patients frequent blood samples were drawn for determination of serum myoglobin total CK and CPK MB isoenzyme (? samples for each marker during 50 hours)

Total CK determination was performed according to the method of Rosalki The CK MB fraction was detected by electrophoresis on cellulose acetate plates For the measurement of CK MB a densitometric method was used by scanning the electrophoretic fraction of MB with the quick scan fluris The amount of CK MB was calculated as a percentage of the total CK activity Serum myoglobin levels were determined by radioimmunoassay using a kit from Nuclear Medical Systems Inc Newport Beach California

We found that significantly elevated serum myoglobin indicative of infarction was present 3 hours following the onset of chest pain in all patients examined and predated elevations of total CPK and CPK MB by 6 to ? hours Utilizing the sensitive radioimmunoassay for detection of myoglobin we found no evidence for the staccato phenomenon previously described

The interval during which the myoglobin assay remained elevated following infarction was found to be up to 50 hours (mean 3? hours) somewhat longer than previously described in the literature (24 hours) On comparing patients with diaphragmatic infarction (group A) to those with anteroseptal infarction (group B) we found significant differences in the myoglobin time curves a five hour plateau observed only in group B patients However the interval during which myoglobin was elevated was longer in group A patients by about 35 hours

A time sensitivity curve was drawn for myoglobin and CK MB which showed that serum myoglobin preceded CK MB for the 50% sensitivity time (by three hours) and for the 100% sensitivity time (by six hours) (Fig 1)

None of the patients serving as the control group had elevated CK MB total CK or serum myoglobin levels above normal

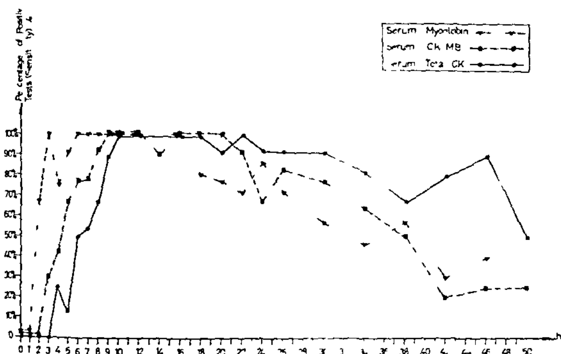

Fig 1 Time (hours) sensitivity curve of serum myoglobin, total CK and CK MB isoenzyme of patients examined.

values (for total CK 90 I U., for CK MB isoenzyme less than 4% of total CK, for myoglobin 85 ng/cc) It is apparent though that myoglobin is a very sensitive indicator of myocardial infarction and since it decreases to normal levels rather quickly it can serve as a valuable aid in the diagnosis of reinfarction and infarct extension CK MB is also a sensitive indicator of myocardial infarction and has the additional quality of high specificity Thus these assays combined will provide a most sensitive and specific early indicator of acute myocardial infarction

The work of Grenadier Keidar and Palant is appreciated Our evidence would tend to agree with theirs concerning the sensitivity of a myoglobin rise as an indicator of myocardial necrosis. In our patients reported all of whom were found to have enzyme evidence and ECG criteria consistent with transmural infarcts there was a detectable rise in serum myoglobin concentration. This suggests that at least in this small group of patients, a myoglobin rise is indeed sensitive for the presence of myocardial necrosis

This is consistent with the accumulated experience which has found a 75 to 100% rate of increased serum myoglobin in comparison with other indicators of myocardial necrosis.

Of interest is their finding of elevated serum myoglobin levels at only 1 5 hours following the onset of the clinical event Although it has been reported that myoglobin concentration will begin to rise within two hours after the ligation of a canine coronary artery previous work suggests this may not be the case in humans In our group there were four patients who did not have elevated myoblobin levels when sampled upon arrival in the emergency room. In our group sampling was done an average of 2.5 hours following the onset of symptoms, and the average time from symptoms to first detectable myoglobin elevation was almost four hours This yields a sensitivity of 50% as an early indication of myocardial infarction in patients who were selected because of ECG evidence of transmural infarctions This is in agreement with the data of Gilkeson and associates who found myoglobin elevation in only 40% of patients seen in an emergency room who subsequently had evidence of myocardial necrosis

This discrepancy may be due to the difficulty in timing of the onset of an out of hospital clinical event rather than the sensitivity of the assay which has been most reliable and quite accurate

The statement that use of early sampling is relatively insensitive is hence based on comparison to confirmatory ECG changes and was intended to discourage the use of myoglobin as an emergency room screening tool However I do concur with Grenadier and co workers assessment that serial myoglobin determinations may be potentially useful as a guide to determining episodes of reinfarctions or infarct extension in patients with acute infarction

Conference and Symposium on Cardiac Arrhythmias

The Second Teaching Conference and Symposium on Cardiac Arrhythmias entitled Mechanisms of Sudden Death will be held on June 15 through 19 1981 in Florence Italy The conference is sponsored by the Department of Medicine University of Oklahoma and by the Instituto di Ricerche Cardiovascolari of the University of Milan For further information contact Dr Benjamin J Scherlag Veterans Administration Medical Center 921 N E 13th St Oklahoma City Okla 73104 Telephone (405) 271-4742

1981 Subspecialty Examination in Cardiovascular Disease

Beginning in 1981 the American Board of Internal Medicine s Subspecialty Examination in Cardiovascular Disease will revert to the former fall date The pertinent dates for 1981 are

Registration Period January 1 1981 to April 1 1981

Examination Date November 10 1981

Deadline for Cancellation October 1 1981

For application forms contact American Board of Internal Medicine 3624 Market St Philadelphia Pa 19104 Telephone (215) 243 1500

formed on 41 acromegalic patients at Mayo in the 60 year period 1919 to 1978 of which 27 cases with adequate clinical data and tissue were included in this pathologic review of the heart in acromegaly Cardiomegaly was common (22 of 27 cases or 81%) and occurred in both hypertensive and nonhypertensive patients The mean heart weight (618 g) of 16 patients who died 10 or more years after the clinical onset of acromegaly was significantly higher ($p < 0.01$) than that (348 g) of 11 patients who died within 10 years of the clinical onset of the disease Disproportionate cardiomegaly (compared to visceromegaly) occurred in about one fourth to one third of the cases The enlarged hearts seldom exceeded 200% (that is twice) of the expected heart weights *according to* the patient s body weight and body length Apart from hypertension other conditions to which cardiomegaly in acromegaly has been attributed were uncommon in our series diabetes 15% (four of 27) significant coronary artery disease 11% (three of 27) and valvular heart disease 19% (five of 27) Myocardial hypertrophy (93% or 25 of 27) and interstitial fibrosis (85% or 23 of 27) were constantly observed Other histological findings which have not been noted in earlier studies included lymphomononuclear cell infiltrate or myocarditis (59% or 16 of 27) and small vessel disease of the myocardium (22% six of 27) Although controversial the possibility of a specific acromegalic cardiomyopathy cannot be discounted on the basis of the currently available evidence

December 1980 Volume 100 Number 6 part 2

Introduction

The articles appearing in this issue were presented at the Symposium on Cardiac Arrhythmias A Decade of Progress—1980 held at Stanford University School of Medicine on May 8 9 and 10 1980 The conference provided a 10-year update on the first such symposium held in 1970 at Elsinor Denmark and featured many of the same participants The symposium as well as this publication were made possible by a generous educational grant from Astra Pharmaceutical Products Inc of Framingham Massachusetts These papers relate to new antiarrhythmic drugs and their comparative study and to other devices for managing patients with life-threatening ventricular arrhythmias unresponsive to treatment by drugs The complete transcript of the symposium will be published later in book form by G K Hall & Co Boston Massachusetts

In Section I Ronfeld Jewitt and Lawrie detail comparative data now available on new antiarrhythmic agents currently under investigation in Europe and the United States While these data are still incomplete for several of the new membrane-active drugs the summaries are the most comprehensive now available

Sections II and III outline studies in patients with coronary artery disease with tocainide an analog of lidocaine with Class I (membrane) activity The antiarrhythmic hemodynamic and toxicity data for patients with acute myocardial infarction demonstrate that tocainide is effective and safe Some patients do develop side effects but discontinuation of treatment is rarely required Long term administration of tocainide in patients with arrhythmias resistant to therapy with available agents is reported by Maloney and Winkle in Section III Horn summarizes safety data from the compassionate clearance protocol and Young presents the results of a series of planned protocols to evaluate tocainide's effectiveness

In Section IV Harrison Zipes Coumel and Schamroth describe their extensive experience with four other promising new antiarrhythmic agents encainide aprindine amiodarone and verapamil

In Section V the interaction of tocainide with beta blocking agents is discussed by Ikram Bigger presents convincing evidence that the Lown classification for premature ventricular contractions has many shortcomings and thus is not helpful in studying newer antiarrhythmic agents Griffin and Mirowski describe early experiences with implantable devices for detecting and electrically terminating arrhythmias

The 1970s truly represented a decade of progress in arrhythmia research New and sophisticated methods for detecting arrhythmias have been developed Pharmacokinetics has become an accepted clinical science and provides us with a more rational means for administering antiarrhythmic agents Drugs with different mechanisms of action have been introduced for trial and offer the hope of effective and safe prophylaxis and treatment of malignant arrhythmias Improved electrophysiologic study techniques have provided understanding of arrhythmia mechanisms and supply a means of designing circuitry for detection and electrical termination of arrhythmias

The 1980s no doubt will see substantial additional progress and excitement in this developing field

Comparative pharmacokinetics of new antiarrhythmic drugs

Robert A Ronfeld, Ph D *Framingham Mass*

The importance of pharmacokinetics to drug therapy is routinely accepted by many clinicians and especially cardiologists today Certainly the pharmacokinetics of a drug are a consideration when a dosage regimen is being designed for a drug and may even be a factor when a choice in drug therapy is being made A working knowledge of a drug s pharmacokinetics can be essential in cardiology since the kinetics of the drug may be altered by the patient s disease state or affected by the multiplicity of drugs the patients may be receiving

The objective of this report is to review the pharmacokinetics of several new antiarrhythmic agents Unfortunately there is a paucity of data on some of the new and possibly significant drugs For the most part these data have been abstracted from the literature Certainly in the coming years, as new analytic techniques are developed much of these data will be modified or viewed as incorrect The basic principles of pharmacokinetics will not be reviewed here since these have been covered satisfactorily in a recent review on antiarrhythmics

The pharmacokinetics of the established antiarrhythmics lidocaine quinidine and procainamide will not be reviewed in detail Because of their short half lives neither of these prototypes has been satisfactory for once or twice daily administration Therefore on the basis of half life alone a new antiarrhythmic agent could be a therapeutic improvement Al o in the steady state each of these three dru h [illegible] metabolite level th it could contribute to their [illegible] erall activity The presence of an active metab [illegible] lite [illegible] ertain ly will make the interpretation of clinical blood or plasma samples more difficult Active metabolites may also increase the interpatient dose response variability In the future there will very likely be a number of antiarrhythmics for the clinician to select from The predictability and convenience of a dosage regimen may then be an important consideration in selecting an appropriate dru

Tocainide

Tocainide and lidocaine have similar pharmacologic and electrophysiologic properties Tocainide is less potent than lidocaine in direct cardiac effects and in central nervous system (CNS) effects Tocainide is a primary amine in contrast to the tertiary amine lidocaine and consequently the free base is 20 times less lipophilic in an octanol water system

Aside from potency the major difference between lidocaine and tocainide resides in their pharmacokinetics Tocainide has a 11 to 13-hour half life in healthy volunteers In patients the mean half life was also 13 hours although the variability was greater than with the volunteers [5] The plasma protein binding of tocainide was constant over the therapeutic range with approximately 50% bound The renal clearance of free drug was approximately equivalent to the expected glomerular filtration rate Typically 40% of an oral dose is excreted unchanged in the urine and 25% is excreted as a glucuronide conjugate of *N* carboxytocainide Total body clearance in both patients and volunteers was 110 to 140 ml/min [5]

Plasma levels above 5 μg/ml are reported to be effective in reducing the frequency of premature ventricular beats Plasma concentrations above 5 0 and 8 3 μg/ml resulted on the average in 70% and 90% reductions in premature beats Other

[illegible] The C V Mosby Co

L

workers reported a 75% reduction in ventricular premature beats when the mean peak blood level was 10 3 µg/ml[7]

There are measurable levels of two metabolites in plasma the previously mentioned glucuronide and lactoxylidide which is the product of oxidative deamination[5] Based on animal pharmacologic data it appears that the metabolites do not contribute to the efficacy or CNS side effects of tocainide

Mexiletine

Mexiletine is a primary amine structurally similar to tocainide Mexiletine has an ether linkage between the benzene ring and alkyl chain whereas tocainide has an amide linkage Because of this structural difference mexiletine has a higher pK and much larger octanol water partition coefficient

The half life of mexiletine was 9 to 12 hours in volunteers In patients mean half lives of 12 and 13 hours were reported as well as a mean of 16 7 hours for patients with acute myocardial infarction The volume of distribution was large and reported as 6 6 and 8 1 L/kg in patients and 500 to 660 L in volunteers Total body clearance was also large at 6 5 and 7 1 ml/min/kg There are conflicting reports on the importance of renal excretion At a normal and unadjusted urinary pH 8% to 20% was excreted unchanged However at a urine pH of 5 renal excretion increased to 40% to 60% and renal clearance increased by a factor of 3 to 4 However the effect of normal physiologic variation in pH remains controversial At least in acute myocardial infarction (AMI) patients there were large intersubject variations in plasma levels with trough levels varying by an order of magnitude[1] The oral absorption and plasma levels were significantly reduced when mexiletine was concomitantly administered with morphine or diamorphine This negative effect on absorption is probably not unique for mexiletine and these investigators suggested that this may also occur with other drugs and antiarrhythmics

Effective plasma levels are reported to be 0 75 to 2 0 µg/ml The incidence of side effects including nausea tremor and hypotension increased at plasma levels above 2 0 µg/ml Mexiletine has been used both intravenously and orally and in the early stages of myocardial infarction Assuming it is effective there is an advantage to using the same drug for initial intra en u dar n tion and mainten ance oral admini tra n I t tunately becau e of the narrow the ape range the intravenous dosage schedu e are plex

Lorcainide

Lorcainide is a new antiarrhythmic in which there have only been preliminary reports on its electrophysiologic and antiarrhythmic p oper ties However the pharmacokinetics of this new antiarrhythmic have been reported in detail

The terminal half life in patients with chronic ventricular premature contractions was reported to be 7 7 hours by two separate groups of investigators There were dramatic differences among subjects with half lives varying from 2 6 to 15.2 hours The volume of distribution was very large at 8 to 10 L/kg The plasma and blood clearances were 1 000 and 1 500 ml/min respectively Only a few percent of the dose was excreted unchanged in the urine Since the clearance is approximately equivalent to liver blood flow we would expect a large first pass effect if metabolism occurs in the liver Based on a single 100 mg oral dose this assumption would appear correct since only 4% of the dose was bioavailable However the bioavailability increased to 30% to 60% with a 200 mg dose and increased to 45% to 200% with multiple 100 mg doses Apparently metabolic saturation occurs with oral administration There are probably two factors contributing to this the concentration presented to the liver can be much higher after an oral dose than after an intravenous dose and at least with multiple dosing there may be product or metabolite inhibition This dose-dependent bioavailability may also occur with drugs such as propranolol and alprenolol which also have high hepatic clearances

The primary metabolite in plasma appears to be a N dealkylated lorcainide or norlorcainide At steady state the norlorcainide lorcainide ratio is approximately 3 with oral administration and 1 with intravenous administration The activity of both compounds measured either as reduction in ventricular premature contractions (VPCs) or QRS widening was similar An effective antiarrhythmic dose appears to be around 100 mg t i d which resulted in steady tate plasma levels of 300 and 900 ng/ml for lorcainide and norlorcainide respectively

M

Aprindine

Aprindine is a Class I antiarrhythmic agent and local anesthetic. It has electrophysiologic properties similar to lidocaine but exhibits greater potency. In two separate studies with volunteers the average half life was 22 hours with a range of 12 to 66 hours.[23] However in patients average half lives of 43 and 50 hours with ranges of 20 to 110 hours were found.[4] Analysis of the data from one volunteer study, in which both cold and radiolabeled drugs were administered, implicated a 70% to 80% bioavailability.[1] This apparently was due to first pass metabolism since the total radioactivity in the plasma was identical for both oral and intravenous doses. The total body clearance in volunteers was approximately 170 ml/min or 2.5 ml/min/kg. In patients it appears to be substantially lower, possibly around 70 ml/min.

Plasma levels effective in suppressing supraventricular or ventricular arrhythmias were generally from 1 to 2 μg/ml. Minor side effects, most frequently dizziness, occurred in the 2 to 3 μg/ml range. Primary metabolites reported have been hydroxylation on the phenyl and indanyl rings and desethylaprindine.[4]

Disopyramide

Disopyramide is an established antiarrhythmic with electrophysiologic properties similar to quinidine. Half lives in volunteers are generally reported to be 7.0 to 8.0 hours. However these half lives may not be real or meaningful since the plasma protein binding of disopyramide changes dramatically with concentration and even within the therapeutic range.

It has been reported that free fraction in plasma increased by 30% to 100% as total concentration increased over the therapeutic range. Because of the nonlinearity in protein binding total plasma concentration and area under the plasma curve are not proportional to dose. However the concentration of nonprotein bound drug in plasma was proportional to dose. It appears that clearance is solely dependent on free drug and consequently changes in protein binding do not affect the free concentration. The half life of the free drug in plasma has been reported to be [illegible] hours. Since the clearance of free drug is constant [illegible] the dose and concentration we would [illegible] changes in binding to be of any consequence [illegible] pharmacologic activity. However, this makes interpretation and dosage adjustment based on total plasma concentration very difficult. The determination of free concentration is not a routine procedure in most laboratories. The therapeutic range for disopyramide in terms of total concentration is reportedly 2 to 7 μg/ml.[3]

Disopyramide phosphate (Norpace) had an 80% to 90% [3,34,35] bioavailability when oral versus intravenous plasma levels were used as a criterion and 90% when urinary excretion was used.[3,36] Because of its short half life it is generally administered at 6 or 8 hour intervals. However a sustained release product has been developed which allows for a 12 hour dosage schedule.[36]

Approximately 50% to 60% of an intravenous or oral dose can be recovered as unchanged drug in the urine.[3,5] The major metabolite appears to be *N*-desisopropyldisopyramide, which accounts for another 25% of the dose in urine. At steady state the plasma levels of the metabolite were approximately one third of the parent compound.

Verapamil

Verapamil has been recognized as an antiarrhythmic agent for many years. Even before specific analytic methods were developed it was recognized that the drug was probably rapidly metabolized since the effective oral dose was 10 to 15 times the required intravenous dose.

Although there has been extensive work on the pharmacology and electrophysiology of this compound, there is a paucity of data on its pharmacokinetics. The only complete report indicates that it has a half life of 3 to 4 hours following a 10 mg intravenous dose. The total body plasma clearance in three subjects 59 to 69 years of age varied from 730 to 1,120 ml/min (mean 12.6 ml/min/kg). Only 5% of the dose was excreted unchanged in the urine. Although it was not done in a crossover fashion, the apparent bioavailability was only 10% to 20% following an 80 mg oral dose. This low availability was apparently due to a large first pass effect since, based on radioactivity, absorption was complete. The volume of distribution was large at 6.0 l/kg and the plasma protein binding was 90%.

As with other drugs with large hepatic clearances such as lorcainide and propranolol, we would expect a large intersubject variability in plasma levels following oral administration

$T_{1/2}$ = elimination half life
†Vd = apparent volume of distribution (Vd_{β} or Vd ...)

There are several metabolites with the N demethylated compound apparently the major metabolite in plasma At steady state this metabolite (norverapamil) and verapamil have approximately equivalent plasma levels It has been suggested that the therapeutic plasma levels are in the range of 100 to 400 ng/ml All of the metabolites are less potent than verapamil Norverapamil had the greatest potency with a 4 6 less vasodilating potency than verapamil

Summary

Table I lists pharmacokinetic parameters for eight of the drugs discussed as well as for quinidine procainamide and lidocaine Data for two of the new agents bretylium and flecainide were not discussed in the text If possible these values are from patients Obviously the individual values especially those in the critically ill patients may differ considerably from the mean values listed Also with a drug such as lidocaine there is a growing amount of evidence suggesting that clearance and the elimination rate constant decrease for patients receiving infusions longer than 24 hours

As stated earlier the three older drugs quinidine procainamide and lidocaine all have less than ideal pharmacokinetic properties for easily maintaining constant blood levels Of course one solution to this has been to develop sustained release dosage forms Of the new drugs listed tocainide mexiletine aprindine and flecainide all have high bioavailability and a half life that may allow for twice daily administration The feasibility of twice daily administration depends on the therapeutic range and the difference between the maximum and minimum concentrations For a half life of 12 to 14 hours we could expect a 1 5 to 2 0 ratio in maximum to minimum concentrations

With disopyramide a half life is listed for both free and total drug Also volume of distribution and clearance are given for total disopyramide in order to be consistent and comparable with the other drugs listed As discussed earlier the value for free disopyramide is the most meaningful

With both verapamil and lorcainide there is a potential for a large first pass metabolism However in the case of lorcainide apparent metabolic saturation results in an apparent 100% bioavailability

These pharmacokinetic data may or may not be used in a clinical setting Very possibly though a blood or plasma sample will be sent to the laboratory for drug analysis When obtaining a drug level questions to ask yourself or the laboratory might be (1) Is the value reliable was the assay method specific and could the blood sampling tube or technique lead to a false value? (2) How can these data along with other clinical and symptomatic data be used to stabilize or improve therapy?

he diagnosis of Ebstein s anomaly is in typical ases easily suspected from physical findings ogether with electrocardiography and x ray xamination In milder forms of the anomaly owever the diagnosis may be difficult without dditional invasive technics such as angiocardiog aphy [1] The lesion shows considerable variation in he pathologic anatomy of the malformation nd its clinical manifestations [3] Since its dvent M mode echocardiography has served as useful tool for the diagnosis of Ebstein s anom ly [1-6] although it is not suitable for the spatial rientation of cardiac structures

Cross sectional echocardiography has also pro vided various clinical information on cardiac natomy and movements Recently apex cross ectional echocardiography has been introduced to display four cardiac chambers side by side[10-1] and a subxiphoid approach has been added to conventional M mode[13-4] or cross sectional echo cardiography [15]

The aim of this study is to describe the abnor malities of the tricuspid valve in Ebstein s anomaly and the chordae tendineae in the right side of the heart using apex and subxiphoid cross sectional echocardiography

Materials and methods

Cross sectional echocardiography was per formed on 11 patients with Ebstein s anomaly isolated or associated with other heart diseases as shown in Table I They ranged in age from two to 43 years Five patients were male and the remain der were female The diagnosis was confirmed by right heart catheterization and angiocardiogra phy in 10 patients and the remaining one was diagnosed by clinical findings and noninvasive diagnostic technics including echocardiography One patient underwent cardiac surgery Two out of the 11 patients showed slight to moderate cyanosis For the control 10 patients with atrial septal defect of secundum type were similarly examined in addition to 10 normal subjects

Cross sectional echocardiograms were obtained by a commercially available Sonolayergraph of Toshiba SSH 11A [1] This instrument was charac terized by its electronic sector scanning system with a wide angle (78 degrees) and 32 element phased array Its resonant frequency was 2 4 MHz The scanning speed was 30 cross sections per second and one frame was composed of 112 scanning lines Furthermore it was possible to simultaneously record dual beam M mode echo cardiograms by sampling from the cross sectional

In eight of the 11 patients it was measured in the four-chamber view from the same plane as the anterior mitral leaflet to the root of the septal tricusp leaflet in end-diastole, using 8 mm cinematography

Abbreviations m = male f = female PFO = patent foramen ovale ASD = atrial septal defect PS = pulmonic stenosis STL = septal tricusp leaflet N.A. = not available

images The effective diagnostic depth was 16 cm

The two dimensional images were obtained in the supine position by directing the cross sectional planes through the cardiac apex and subxiphoid area

Fig 1 shows the position of the transducer and the direction of the ultrasonic beam An apical four chamber view was obtained by orienting the transducer from the cardiac apex in the direction *A*

This cross section readily provided a four chamber view so as to permit visualization of the interventricular septum connected with the interatrial septum in the middle of the images with both ventricles and atria side by side

An apical three chamber view was recorded by orienting the transducer in the direction of *B* which was nearly perpendicular to the cross sectional plane A for the apical four chamber view This cross section provided a three chamber view of the right side of the heart namely the atrialized and functional right ventricles and the right atrium eliminating the left sided heart chambers

Furthermore a subxiphoid cross section was obtained by placing the transducer horizontally below the xiphoid process *C* and occasionally along the left costal margin *D* to visualize the wider area encompassing the right ventricular cavity to the left sided heart

Results

Our data were divided into two major categories the first was the assessment of the downward displacement of the septal tricuspid leaflet in a four chamber view through the cardiac apex and the second was the subxiphoid approach to the evaluation of the subvalvular apparatus such as the chordae tendineae inserting into the tricuspid valve

1 Apex cross section

a *Four chamber view* An apical four chamber view was obtained in all the patients Fig 2 shows a four chamber view by apex cross section in a 35 year old male (H S) with Ebstein s anomaly The septal tricuspid leaflet *(STL)* is displaced downward into the right ventricle resulting in the formation of the atrialized right ventricle *(AT RV)* and functional right ventricle *(FRV)* The anterior tricuspid leaflet *(ATL)* is elongated but not displaced from the tricuspid valve ring Fig 3 shows another example of the four chamber view in a 21 year-old female patient with Ebstein s anomaly and patent foramen ovale The STL is similarly displaced downward into the right ventricular cavity

The displacement of the STL was measured in the four chamber view from the same plane as the anterior mitral leaflet *(AML)* to the root of the STL in end-diastole using 8 mm cinematography The displacement ranged from 1 4 to 3 2 cm with an average of 2 1 ± 0 5 cm in eight patients as shown in Table I However the downward deviation of the STL could not be measured in three patients in the four chamber view In one of these three patients (M T) the rudimentary STL was detected by angulating the probe in the direction *B* as shown in Fig 1 In contrast the four chamber view disclosed no displacement of

280 patients. Entry into the study was 2 weeks after acute myocardial infarction (AMI). Patients were followed up for 1 year. Ventricular arrhythmias totally disappeared in 50% of aprindine patients and in 20% of the placebo group. There was no difference in death rate between the two groups. Cholestasis (three patients) and agranulocytosis (two patients) appeared in the aprindine group. Somewhat similar results have been presented by Hutton using tocainide. A comparable study with mexilitine, conducted by Julian et al (personal communication, 1979), has also shown the same type of result, that is, reduction or abolition of ventricular arrhythmias compared with placebo therapy but no significant reduction in death rate.

Amiodrone

Amiodrone is a Class III drug that is reputed to be effective against ventricular fibrillation. It has also been shown to be especially useful in the long term prophylaxis of Wolff Parkinson White syndrome and ventricular arrhythmias, but certain side effects (corneal deposits and dysfunction of thyroid gland) have inhibited its general use. There is no published information regarding its efficacy compared with any of the preceding new antiarrhythmics.

Verapamil

Verapamil, a Ca antagonist, is useful in the acute management of supraventricular tachycardias in acute myocardial ischemia or ventricular arrhythmias. Once again there have been no comparative trials with verapamil and the other newer antiarrhythmic agents, particularly in ventricular arrhythmias.

Discussion

The reduction or abolition of ventricular arrhythmias achieved with various drugs, such as mexilitine, tocainide, and aprindine, without an accompanying reduction in death rate is rather disappointing, indicating that the effectiveness of an antiarrhythmic agent against so-called warning ventricular arrhythmias does not mean that they are effective against VF or sudden death. On the other hand, it is interesting to note that effectiveness against sudden death in postinfarct patients has been claimed for several agents (not regarded as antiarrhythmic agents), such as sulfinpyrazone, aspirin, and persantin. The explanation for this divergence of results remains to be elucidated.

Summary

A number of new antiarrhythmic drugs have been introduced in the past decade. They have been extensively studied, mainly in patients with AMI and for short periods following this event. No long term comparative trials have been reported, although some medium term studies have been completed and longer term studies are underway. Most of the new agents have been demonstrated to be effective in diminishing or suppressing serious ventricular arrhythmias, but this has not been associated with a corresponding fall in the death rate. To date none of these drugs, except perhaps beta blockers, has been shown to lower the risk of sudden death. Nevertheless, the question remains as to whether a small reduction in the mortality rate warrants widespread use of any of the current drugs for the prevention of sudden death. There is a great need for long term comparative trials with patients properly stratified to see which agent is most effective and in what particular patient group.

Hemodynamic effects of newer antiarrhythmic drugs

David E Jewitt MB *London England*

The aim of antiarrhythmic drug therapy is to terminate or suppress specific arrhythmias and improve cardiovascular function Short term studies of the new Class I drugs encainide mexiletine and tocainide have demonstrated only minor falls in cardiac index with modest rises in mean aortic pressure In contrast disopyramide has been shown to depress myocardial function in both animals and patient studies Heart failure may be precipitated by therapy with disopyramide and electromechanical dissociation has been reported Class II agents with beta adrenergic blocking actions all produce a degree of myocardial depression Atenolol resembles propranolol in patients with coronary artery disease in its hemodynamic effects whereas acebutolol is less of a depressant resembling practolol The Class III agent amiodarone has only a mild depressant effect associated with a reduction in afterload and an increase in coronary blood flow The Class IV agent verapamil which is a calcium channel blocker has potent myocardial depressant actions and causes peripheral vasodilatation Hypotension heart failure and shock have been precipitated particularly in patients receiving beta blocking drugs concurrently While all the new antiarrhythmic drugs currently studied will cause some degree of hemodynamic depression in an appropriately high concentration present investigations suggest that particular caution needs to be taken when disopyramide aprindine atenolol and verapamil are administered either acutely by the intravenous route or chronically by the oral route

The aim of successful antiarrhythmic drug therapy is to terminate or suppress a specific arrhythmia and improve cardiovascular function This action may be achieved by the suppression or termination of arrhythmias that are either directly life threatening or the precipitating cause of cardiovascular failure An ideal antiarrhythmic drug will achieve this objective without general or cardiovascular side effects in therapeutic dosage It is important therefore to document the hemodynamic effects of newer antiarrhythmic drugs at clinically relevant concentrations and to confirm that when arrhythmia termination is achieved cardiovascular function is not compromised These studies need to be performed in patients with heart disease with and without evidence of impaired cardiac function

In this report the hemodynamic effects of newer antiarrhythmic drugs will be reviewed in groups according to their predominant experimental electrophysiologic effect as described in the classification of antiarrhythmic drugs by Vaughan Williams[1] and Singh and Vaughan Williams

an infusion of 1.5 mg/kg mexiletine had minor effects on cardiovascular hemodynamics only. There was a small but significant rise in left ventricular end-diastolic pressure. During hand grip isometric exercise, there were small but significant falls in cardiac output and peak left ventricular dP/dt associated with a small increase in left ventricular end-diastolic pressure. This lack of major hemodynamic effect was confirmed in studies of 16 patients with valvar heart disease.[4] In contrast, Saunamaki observed further impairment of myocardial function in three of six patients with ischemic heart disease and previous heart failure who were given mexiletine intravenously, achieving a plasma level greater than 1 $\mu g/ml$.

In many respects mexiletine is comparable to lignocaine hemodynamically when given intravenously. It is concluded that intravenous administration of mexiletine in clinically effective doses produces little or no adverse hemodynamic effects in the absence of clinical evidence of heart failure. When heart failure is present, caution is necessary during its intravenous administration. In controlled studies of long term oral mexiletine in the prophylaxis of ventricular arrhythmias over a 3-month period, there has been no evidence that cardiac failure was precipitated.

Disopyramide. A negative inotropic effect has been demonstrated when disopyramide is administered intravenously to experimental animals and man. Thus in a placebo controlled study in 18 patients with recent myocardial infarction, 100 mg of disopyramide intravenously over 5 minutes significantly prolonged the pre-ejection period and increased the ratio of the pre-ejection period to left ventricular ejection time for more than 15 minutes following drug administration. However, if the rate of administration of the same dose was prolonged over 10 minutes, a reduced effect was seen.

In a study of 10 patients with cardiac disease (six with normal and four with abnormal left ventricular function), 1.5 mg/kg of intravenous disopyramide over 2 minutes decreased cardiac index, stroke volume, and stroke work index to a greater degree in those patients with abnormal function, both during spontaneous sinus rhythm and when heart rate was maintained stable by atrial pacing.

In a recent study, electromechanical dissociation has been reported following the administration of disopyramide to patients with severe congestive failure and renal insufficiency in whom the drug was being administered to control recurrent and resistant ventricular tachycardia. This indicated the need for dosage reduction in the presence of renal insufficiency and extreme caution. The importance of hemodynamic depression following disopyramide administration was demonstrated when 16 patients with disopyramide induced cardiac decompensation were reported out of a total of 100 patients consecutively treated with the drug.

Whereas in patients without established left ventricular dysfunction, disopyramide is relatively safe orally, the intravenous route should be used with caution. In the presence of left ventricular dysfunction, disopyramide is potentially a hazardous agent not only intravenously but also during chronic oral therapy, and careful clinical observation is mandatory.

Tocainide. In a study of 12 patients with established heart disease, 11 of whom had compensated left ventricular dysfunction, small increases in left ventricular end diastolic pressure have been noted, although no major depression of overall ventricular function was seen with tocainide plasma concentrations within the known therapeutic range. An increase in systemic and pulmonary arterial pressure was observed in this study, secondary to increases in vascular resistance in both beds. In patients with valvar heart disease studied echocardiographically in a control study of oral tocainide, no evidence of myocardial depression was observed.

Tocainide therefore, like lignocaine and mexiletine, appears to cause minimal myocardial depression at therapeutic plasma concentrations. Further information on the hemodynamic effects of tocainide are reported elsewhere in this symposium.

Encainide. This new antiarrhythmic agent has been shown electrophysiologically to have important Class 1 actions.[2] Hemodynamically, it has been studied in patients at the time of catheterization by Harrison.[11] In this study, 17 patients were given encainide intravenously, 12 of whom had coronary artery disease and 5 of whom had primary myocardial disease. There was a significant increase in heart rate and systemic vascular resistance following encainide 0.9 mg/kg body weight intravenously with a modest decrease in cardiac and stroke index. Left ventricular end

II Evaluation of antiarrhythmic drugs in acute myocardial infarction

Placebo controlled study of prophylaxis of ventricular arrhythmias in acute myocardial infarction

Ronald W F Campbell M D *Newcastle upon Tyne England*

Successful prophylaxis of ventricular arrhythmias in acute myocardial infarction m ght ach eve a major reduction in mortal ty of this condition No sat sfactory drug is yet ava lable but many new antiarrhythmic agents are being tested in this role Such placebo controlled investigations in the earl est phase of myocardial infarction encounter unique problems of study design drug pharmacokinetics study conduct and data analysis

Identification of a safe effective antiarrhythmic drug for the prophylaxis of ventricular arrhythmias associated with acute myocardial infarction is currently an important goal of cardiologic research A placebo controlled study is generally considered the optimal design for evaluation of new therapies and is probably essential in this clinical situation which is associated with high natural mortality and morbidity rates but the complex and rapidly changing pathophysiology of acute myocardial infarction presents particular difficulties in the design conduct and analysis of placebo controlled investigations

Objectives and justification of placebo controlled studies

The aim of a placebo controlled study for the prophylaxis of ventricular arrhythmias in acute myocardial infarction is to define an antiarrhythmic drug which by preventing serious ventricular arrhythmias might improve morbidity or mortality rates Ventricular fibrillation and hemodynamically significant ventricular tachycardia are the arrhythmias of particular importance in this context The study should clearly identify patients for whom therapy was beneficial and evaluate drug safety in all treated individuals

Administration of a placebo to patients with acute myocardial infarction is acceptable only if there is no active agent of proved benefit that is being withheld because of the study Propranolol lidocaine and disopyramide have been reported to reduce the mortality rate in acute myocardial infarction Further investigations with propranolol failed to confirm the original findings The study of intramuscular lidocaine was flawed by a statistically significant excess of patients who received active therapy and a further investigation of lidocaine given by this route failed to show benefit The findings of the study of disopyramide have been the subject of considerable criticism and cannot be accepted until further corroborative investigations are reported

A statistically significant reduction of primary ventricular fibrillation by means of high dose intravenous lidocaine has been reported The hospital mortality rate was unaffected Although there is no corroborative controlled study evidence uncontrolled investigations appear to support the original conclusions However an earlier investigation using intravenous lidocaine documented an increased evidence of A V conduction disorders producing prolonged ventricu

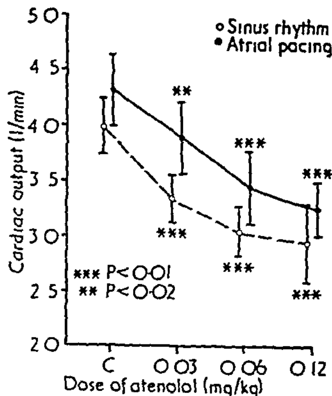

Fig 1 Mean changes in cardiac output in patients receiving graded doses of atenolol during sinus rhythm and during atrial pacing at constant rate (From Robinson C Jackson PG Fisk C J with DF Haemodynamic effects of atenolol in patients with coronary artery disease Br Heart J 40 22-8 1978

diastolic pressure fell significantly Changes in cardiac index were most marked in the nine patients with low control cardiac index levels The mild depression seen mainly in patients with impaired cardiac function at rest suggests that this drug s hemodynamic effects will not detract from its potential value However more information is required on the effects of this drug intravenously and orally on systemic and coronary hemodynamics in patients with established heart disease with and without prior left ventricular dysfunction

Drugs with Class 2 antiarrhythmic actions

The hemodynamic effects of propranolol have been extensively investigated in the past and it has become the agent against which all new Class 2 antiarrhythmic drugs with beta blocking actions are compared Hemodynamically practolol has been shown intravenously to be an effective antiarrhythmic drug producing less hemodynamic depression However development of the oculomucocutaneous syndrome following its oral use has restricted its subsequent therapeutic value although it remains a useful agent intravenously in intensive and coronary care units Several new beta adrenergic blocking drugs all with comparable antiarrhythmic value particularly in the management of supraventricular arrhythmias have been introduced Here attention will be limited to two such agents atenolol and acebutolol

Atenolol Atenolol has been shown to possess cardioselectivity equivalent to that of practolol and like practolol atenolol lacks membrane-stabilizing properties In contrast however atenolol does not possess intrinsic sympathomimetic activity [15] Its antiarrhythmic efficacy has been established in animal studies Its hemodynamic effects have been studied in a group of eight patients with established obstructive coronary artery disease [1]

A dose related decrease in heart rate and cardiac output was shown to be produced without a significant change in systemic arterial pressure when atenolol, 0 03 to 0 12 mg/kg body weight intravenously was given over a total of 6 to 10 minutes (Fig 1) However in contrast to the previous findings with practolol and like those observed with propranolol there was a significant fall in cardiac output after atenolol which was not purely rate dependent (Fig 1) Left ventricular end diastolic pressure did not change significantly but there was a dose related reduction in the maximum rate of rise of left ventricular pressure (dP/dt) after atenolol Systemic vascular resistance increased significantly after atenolol in the patients at rest and this is comparable to the findings after intravenous propranolol but contrasts with those after intravenous practolol in similar patients [1]

The overall hemodynamic effects of atenolol therefore more closely resemble those of intravenous propranolol than those of intravenous practolol It seems likely that the relatively minor hemodynamic effects that follow intravenous practolol reflect the combination of cardioselectivity and intrinsic sympathomimetic activity in the same agent whereas cardioselectivity alone as in atenolol results in hemodynamic effects similar to those of propranolol Atenolol is therefore of potential value as an antiarrhythmic drug orally but does not have the hemodynamic advantages of practolol for intravenous administration

Acebutolol Acebutolol is a newer beta adren

lar asystole in lidocaine treated patients who were suspected of having sustained infarction but in whom this diagnosis was not later confirmed[11]

The lack of a safe effective antiarrhythmic drug for the prophylaxis of ventricular arrhythmias in patients suspected of acute myocardial infarction justifies continued placebo controlled studies of prophylactic antiarrhythmic therapy

Study design

Study population In clinical practice an acceptable effective drug for the prophylaxis of ventricular arrhythmias would be given to a relatively unselected patient population with suspected acute myocardial infarction However the high early incidence of ventricular arrhythmias in acute myocardial infarction[1] allows identification of patients who are at particular risk and therapy may be more economically evaluated by restricting administration to this group

Shock cardiac failure and conduction disorders are common reasons for exclusion of patients from studies It is probably not justified to expose such patients to the risk of antiarrhythmic therapy that may aggravate these complications of acute myocardial infarction Other acceptable conditions of exclusion include situations where the pharmacokinetics of the drug may be grossly abnormal e g in patients with hepatic or renal disease Care must be exercised to minimize the exclusion criteria or therapy will be evaluated in such a restricted patient population that the findings will have little practical applicability

Predefined serious ventricular arrhythmias (ventricular fibrillation and hemodynamically significant ventricular tachycardia) death and possible unwanted effects of therapy or infarction are premature end points of study and usually involve withdrawal of the patient Patients who are protocol violations should also be withdrawn when it is recognized that they have not satisfied the entry criteria They will have received inappropriate therapy and it is essential that any consequences of drug administration to them be reported Nonconfirmation of infarction is the most common cause for early withdrawal This is usually unavoidable as it is desirable that selected patients be admitted into the investigation as soon as possible after identification However within the first few hours after the onset of symptoms definite confirmation of acute myocardial infarction is available for only a few patients since the ECG often will show no or nonspecific ST changes and enzyme levels are not usually available instantly In consequence a placebo controlled study employing early randomization of patients will probably include a sizable proportion who in retrospect have no sustained acute myocardial infarction but whose progress in the study cannot be neglected

Therapeutic considerations Prophylactic interventions against serious ventricular arrhythmias particularly primary ventricular fibrillation, must be rapid in their onset In theory intravenous administration of a drug could achieve near instantaneous therapeutic plasma levels but in practice this is difficult to accomplish and toxic effects are often encountered An additional disadvantage is the need for skilled medical or paramedical attendance to establish this route of administration By contrast intramuscular administration can be undertaken by unskilled people and even by the patient himself with a pressurized injector and by using a suitable site therapeutic plasma levels can be obtained almost as quickly as with intravenous therapy The maintenance of an adequate plasma level of the drug after the initial intramuscular administration can present difficulties and may involve additional intramuscular administration or recourse to either intravenous or oral doses Oral therapy has the attraction of easy administration but gastrointestinal absorption may be slow and reduce the effectiveness of the drug Both acute myocardial infarction and the management of its pain by narcotic analgesia reduce the rate of gastric emptying thus delaying drug absorption[11] This factor probably precludes the successful use of oral antiarrhythmic therapy in reducing the incidence of serious ventricular arrhythmias in acute myocardial infarction

The duration of administration of therapy can vary from a few hours to many days or even months If the prophylaxis of primary ventricular fibrillation is the major objective of the study then the duration of therapy might be confined to the first 24 hours after the onset of symptoms since thereafter the incidence of this arrhythmia is low Continuation of therapy beyond the first 24 hours after the onset of symptoms permits examination of the drugs effect on the arrhyth

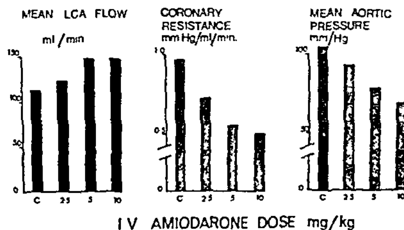

Fig 2 Mean coronary hemodynamic changes following graded doses of intravenous amiodarone in eight open-chest anesthetized dogs LCA = left coronary artery

ergic blocking drug that has been shown to be approximately one-eighth as potent as propranolol as a beta antagonist It exerts membrane stabilizing effects similar to those of propranolol It does have a degree of cardioselectivity and also some intrinsic sympathomimetic activity although less marked than that seen with practolol Hemodynamically in doses of 0.6 to 1 mg/kg it has been shown to cause modest reductions in cardiac output and ejection fraction when administered postoperatively to patients who have undergone coronary artery bypass surgery

In a recent study in patients with obstructive cornary artery disease acebutolol in doses of 0.6 mg/kg body weight intravenously given over 2 minutes produced only minor systemic hemodynamic effects The changes in coronary sinus blood flow and coronary vascular resistance were also minor and there was no significant change in myocardial oxygen consumption It is important to note that the lactate extraction ratio in these patients during control atrial pacing to angina was −14% ± 4.5% indicating lactate production This was reversed to lactate extraction with a mean value 10% [illegible] 2 at the same atrial pacing rate after the drug Acebutolol therefore resembles practolol more closely than propranolol or atenolol hemodynamically It is likely that this reflects the possession of both weak intrinsic sympathomimetic activity and cardioselective properties It is a useful alternative to practolol when an intravenous beta blocking drug is indicated for the termination of supraventricular arrhythmias

Drugs with Class 3 antiarrhythmic actions

Amiodarone Amiodarone originally introduced as an antianginal drug is the principal agent with Class 3 properties and possesses unique electrophysiologic properties Its antiarrhythmic effects were summarized by Rosenbaum et al The effects of amiodarone on cardiac and coronary hemodynamics were studied in open-chest anesthetized dogs by Singh et al Intravenous amiodarone over the concentration range of 2.5 to 10 mg/kg body weight produced a dose related decrease in heart rate and total peripheral resistance with a decrease in cardiac contractile force and left ventricular dP/dt Despite this the left ventricular cardiac output increased progressively No significant fall in left ventricular end-diastolic pressure occurred up to doses of 5 mg/kg body weight intravenously but at 10 mg/kg intravenously modest increases in left ventricular filling pressure occurred These findings in association with the fall in left ventricular contractile force and left ventricular dP/dt suggested a modest negative inotropic effect The increase in cardiac output with increasing doses probably reflects the marked reduction in resistance to left ventricular ejection which results from the systemic vasodilatation

mias encountered in this later phase of infarction but few of these rhythm disturbances will be of a life threatening type

Conduct of the study

Informed consent The value and medicolegal significance of informed consent is controversial [3] but is essential and appropriate for the majority of clinical research investigations None theless it is questionable whether it is justified to seek informed consent from patients with acute myocardial infarction when they require rest sedation relief of pain and reassurance rather than an academic discourse on the implications of enrollment into a placebo controlled prophylactic antiarrhythmic drug study Informed consent implies a patient s understanding of the conventional alternative to the proposed study However there is no standardized arrhythmia management high dose prophylactic intravenous lidocaine aggressive treatment of warning arrhythmias and management only of hemodynamically significant arrhythmias are three diverse but widely practiced approaches Perhaps in acute myocardial infarction protocol approval by fellow practitioners and ethical committees extensive elective drug testing in a variety of clinical situations and the propriety and compassionate concern of the investigating physician could reduce the necessity for informed consent

Arrhythmia data acquisition and analysis As the early high mortality rate of acute myocardial infarction largely reflects primary ventricular fibrillation it is possible to design a study that does not require continuous recording or monitoring of the ECG However most studies do employ some form of ECG analysis Following the demonstration of the inaccuracy of observer monitoring of the ECG continuous ECG recording and sophisticated analysis is commonplace These recordings can present particular analysis difficulties as the changing shape of the QRS ST and T waves associated with acute infarction can cause false triggering of arrhythmia analyzers which must also cope with a high incidence of artifact due to the restlessness of the patient sweating and poor adhesion of electrodes Continuous ECGs must contain clear identification of at least the time of drug administration and should preferably record clock time continuously throughout the study

Use of drugs The study medication would be the only drug administered in an ideal prophylactic antiarrhythmic investigation but in practice this is rarely the case Restriction of the use of additional antiarrhythmic therapy is however highly desirable The role of the coronary care unit in the monitoring and rapid treatment of significant arrhythmias assumed greater importance with the suggestion that a variety of ventricular arrhythmias appeared to predict the development of ventricular fibrillation and that suppression of these events could abort ventricular fibrillation ' Were this true then aggressive suppression of these ventricular arrhythmias would be justified and the task of evaluating drugs for the prophylaxis of ventricular fibrillation might be made easier as reduction of these events could be a criterion of drug effectiveness However warning arrhythmias appear not to foretell ventricular fibrillation and have been reported as frequently in patients who do not progress to ventricular fibrillation as in those who do The justification for treating these arrhythmias then is their hemodynamic consequence which is probably insignificant for isolated ventricular ectopic complexes of almost any frequency multiform ventricular ectopic complexes ventricular ectopic complex pairs R on T ventricular ectopic complexes and perhaps short runs of ventricular tachycardia If these arrhythmias can be tolerated without treatment the attendant reduction in use of antiarrhythmic drugs would greatly improve the evaluation of prophylactic antiarrhythmic drugs Sustained or hemodynamically significant ventricular arrhythmias such as ventricular fibrillation or prolonged episodes of ventricular tachycardia require treatment when they occur

Other hemodynamically significant arrhythmias that may require intervention include atrial fibrillation atrial flutter sinoatrial disorders and A V conduction problems which can be a consequence of infarction but which should be considered as potential unwanted effects of the study medication Similarly bundle branch block and QRS complex axis shifts should be noted although attitudes vary regarding the need for immediate management or for withdrawal from a prophylactic antiarrhythmic drug study

Antiarrhythmic drugs are not the only drugs that can interfere with the evaluation of antiar

Direct intracoronary injections of amiodarone 0 25 to 4 mg which were doses too small to exert systemic effects produced a dose related increase in coronary blood flow associated with a fall in coronary vascular resistance This coronary vasodilator effect was also seen during intravenous amiodarone injections in doses of 2 5 to 10 mg/kg body weight In this instance the increasing coronary blood flow and fall in coronary vascular resistance was achieved despite a fall in systemic arterial pressure (Fig 2) Experimentally therefore amiodarone creates a favorable balance in oxygen supply and demand by affecting the major determinants of myocardial oxygen consumption These experimental observations have since been confirmed in 16 patients undergoing coronary arteriography for chest pain 14 of whom had obstructive coronary artery disease

These clinical studies therefore confirm that amiodarone used intravenously is a powerful systemic and coronary vasodilator and is relatively safe for use in the acute therapy of patients with cardiac arrhythmias However antiarrhythmic therapy with amiodarone is generally indicated and most effective by the oral route To date long term hemodynamic studies using this route of administration have not been published however there are no reports of cardiac failure being precipitated

Drugs with Class 4 antiarrhythmic actions

Verapamil The prototype of this group of agents that selectively inhibit membrane transport of calcium is verapamil It is a synthetic papaverine derivative initially introduced as a smooth muscle relaxant which has potent peripheral and coronary vasodilator actions In isolated heart muscle it does not exhibit Class 1 2 or 3 electrophysiologic actions and therefore a separate category of action emphasizing the antagonism of the slow inward calcium currents was proposed Its main locus of action appears to be superficially located membrane storage sites for calcium In clinical electrophysiology its primary site of action is on the A V node where A V conduction time is increased du   depression of the slow response fibers

Verapamil has a marked negative inotropic effect on isolated heart muscle In man the most comprehensive study of its hemodynamic effects was reported by Singh and Roche In 20 patients with coronary artery disease or rheumatic valve lesions they found the peak effects of intravenous verapamil in a dose of 10 mg occurred between 3 and 5 minutes after the completion of the injection and had disappeared by 10 minutes Mean arterial pressure and systemic vascular resistance fell significantly with an increase in left ventricular end-diastolic pressure and a reduction in left ventricular dP/dt_m Heart rate and cardiac index increased but these changes were not statistically significant These results therefore indicated that intravenously verapamil does have a negative inotropic effect but it is minimized by its peripheral vasodilator action in reducing afterload Caution is clearly necessary particularly when verapamil is administered to patients with significant myocardial decompensation and in patients with myocardial infarction as in these patients there are little data available on the hemodynamic effects of the drug

The incidence of hemodynamic side effects is much higher in patients previously on beta adrenergic blocking agents who are given verapamil either intravenously or orally The negative inotropic actions and depressant effects on impulse generation of the beta blocking agents and those of verapamil summate Severe hypotension coupled with bradycardia and asystole may result

The administration of verapamil intravenously is therefore potentially hazardous in the presence of impaired left ventricular function and particularly where prior administration of beta adrenergic blocking drugs has been employed In the absence of left ventricular impairment the mild hemodynamic changes observed are unlikely to be clinically important

rhythmic therapy The variety of clinical problems encountered in acute infarction encourages the use of drugs and of those commonly administered narcotic analgesics diuretics potassium supplements antiemetics hypnotics sedatives tranquilizers atropine digoxin and beta adrenergic blocking drugs may all modify the natural course of ventricular arrhythmias, including ventricular fibrillation and may alter the effect of the antiarrhythmic drug under investigation Many protocols have failed to standardize or establish criteria for the use of these therapies and often reports have omitted information regarding the incidence of use of these drugs during the study

Termination of the study At the termination of a prophylactic controlled study all data of all patients should be analyzed before allocation codes are broken unless a sequential statistical approach has been adopted A theoretic possibility exists that a patient who has received active therapy may be at particular risk of arrhythmias on termination of therapy either by exposure of a previously suppressed event or by a rebound phenomenon Clinical experience suggests that this problem is not significant

Analysis of data

Group comparability The many risk factors related to the natural history of acute myocardial infarction should be balanced in both placebo and active therapy groups Age sex site of acute myocardial infarction time from onset of symptoms to inclusion in the study estimates of infarct size smoking history the number of previous myocardial infarctions and previous therapy are among those commonly examined The time from the onset of symptoms to inclusion in the study is probably the most important feature and is usually recorded for each group as a mean time with the standard deviation However this type of comparison can conceal important imbalances between patient groups and these are relevant in considering ventricular arrhythmias which are critically time dependent A profile of the number of patients admitted within defined time periods from the onset [illegible] would allow better comparison

Analysis of patients who have [illegible] sustained acute infarction All patients [illegible] placebo controlled study of antiarrhythmic therapy in acute myocardial infarction [illegible] rted in the final analysis Those who are entered [illegible] who are shown not to have sustained acute myocardial infarction will have received inappropriate therapy It might be anticipated that an active drug would have little or no beneficial effect in these patients who probably have a low risk of developing serious ventricular arrhythmias, but these individuals may be particularly susceptible to the adverse effects of the study drug In addition, the dose and route of administration of the active drug will have been chosen to achieve rapid therapeutic plasma levels in patients with acute myocardial infarction but the pharmacokinetics of the drug may be markedly different in patients without this diagnosis Analysis of nonmyocardial infarction patients should include documentation of the incidence not only of unwanted symptoms but also of cardiac failure sinoatrial disorders A V conduction disorders shock and analysis of ventricular arrhythmias as performed for those patients with definite acute myocardial infarction

Extrapolation of results Although tempting, it is not justified to extrapolate that a drug highly effective in suppressing ventricular tachycardia will be useful in the prevention of ventricular fibrillation Primary ventricular fibrillation and ventricular tachycardia have distinctly different time courses in acute myocardial infarction and their mode of initiation is strikingly different

Conclusions

Since 1961 there have been over 14 placebo controlled studies of antiarrhythmic therapy in acute myocardial infarction The drugs investigated have included procainamide [illegible] quinidine [illegible] propranolol [illegible] lidocaine [illegible] disopyramide [illegible] mexiletine,[illegible] and tocainide [illegible] Few have restricted inclusion to patients seen in the earliest hours of infarction and analysis of events in nonmyocardial infarction patients has been rare There is no standardized study design for the placebo controlled investigation of prophylactic antiarrhythmic drug therapy in acute myocardial infarction but improved knowledge of the natural history of arrhythmias in acute infarction and awareness of the practical difficulties and implications of identifying a successful management dictate careful consideration of the many special aspects of research of this clinical problem

Comparison of newer antiarrhythmic agents

T D V Lawrie M D *Glasgow Scotland*

In the past decade a number of new antiarrhythmic drugs have been introduced They have been extensively used in the acute phase of myocardial infarction Few if any long term comparative trials of these newer agents have been reported Most of these newer agents have been shown to be able to reduce the frequency of ventricular arrhythmias but not the mortality rate Beta blockers and some antiplatelet adhesive drugs however have reduced the mortality rate following myocardial infarction There is a need for long term properly stratified trials of these effective agents

The main aim of chronic antiarrhythmic therapy is to reduce or prevent the occurrence of ventricular fibrillation (VF) and sudden death thus reducing the mortality rate Certain antiarrhythmic agents such as quinidine procainamide and phenytoin have been extensively studied—especially in coronary heart disease where VF and sudden death are most common Quinidine has been shown to decrease ventricular ectopic beats (VEBs) in acute myocardial infarction but there is no convincing evidence that it has materially reduced the mortality rate from sudden death in such patients in the long term in fact in some patients it has been shown to precipitate VF In contrast procainamide does appear to have a favorable effect not only in reducing the frequency of VEBs but also the frequency of sudden death A major problem resulting from its long term use however is its ability to produce a systemic lupus erythematosus-like syndrome in a large proportion of patients Phenytoin appears to be less effective than procainamide in preventing serious ventricular arrhythmias

Furthermore the numerous studies involving these drugs have shown that the dosage schedule for each drug requires adjustment for each individual patient and side effects are not infrequent There is therefore a need to look for newer antiarrhythmic agents that not only diminish or suppress ventricular arrhythmias but also prevent VF and sudden death have a simple dosage regime and have few or no side effects when taken over a prolonged period

There is a dearth of information on long term comparative trials of the new antiarrhythmic agents It is therefore necessary to review the various publications on each agent and thereby try to gain some knowledge about their relative efficacy

Beta blocking agents

Although beta adrenergic blocking agents have been in use for 10 to 15 years mainly for the treatment of angina pectoris and hypertension, they may also be regarded as falling into the category of newer antiarrhythmic agents Practolol alprenolol oxprenolol and propranolol have been used in long term secondary prevention studies following acute myocardial infarction To date the results of 15 studies in Europe have been reported In 11 of the studies[1-11] the agent was started within 24 to 48 hours of the clinical onset of infarction In the remaining four studies treatment was started 2 weeks or more after the onset of infarction[1-1] It is not possible to summarize in this presentation the results of all of these studies which varied in design selection of patients and duration of treatment Furthermore the effect of the particular agent on preventing sudden death as opposed to reinfarction is not clear from the presentation of results We propose to discuss briefly the major studies with positive findings

Hemodynamic and antiarrhythmic effects of tocainide in patients with acute myocardial infarction

Olof Nyquist M D Gunilla Forssell M D Rolf Nordlander M D and Karin Schenck Gustafsson M D *Stockholm Sweden*

In order to evaluate the hemodynamic and antiarrhythmic efficacy of tocainide studies were performed in patients suffering acute myocardial infarction Intravenous tocainide was administered over a 15 minute period in order to determine its acute effects and subsequently in a randomized double blind study with placebo control to determine its effects over a 24-hour period in acute myocardial infarction Tocainide resulted in a significant decrease of frequent and complex ventricular arrhythmias acutely and had only minimal effects of hemodynamics in most patients In the long term studies tocainide produced no adverse hemodynamic effects when compared with placebos

Tocainide is a new antiarrhythmic drug that is chemically similar to lidocaine but in contrast is *effective in the treatment of* ventricular arrhythmias when given orally[1-4] Although some of the patients in previously reported studies had coronary artery disease the antiarrhythmic circulatory and adverse effects of tocainide have not been evaluated in patients with acute myocardial infarction (AMI) As tocainide will be used in patients with AMI the present study was performed to evaluate the hemodynamic and antiarrhythmic effects of the drug and patient tolerance in this situation

Methods

Patients with AMI and frequent (more than five per minute) paired multifocal early premature ventricular contractions (PVCs) and/or ventricular tachycardia (runs of three or more PVCs rate over 100 beats/min) were studied within 24 hours of the onset of symptoms No antiarrhythmic agents other than tocainide were given before or during the study period Bedside catheterization was performed in the coronary care unit (CCU) and the right atrial pulmonary artery and aortic pressures were recorded continuously All pressures are given as means of at least five breathing cycles Cardiac output was determined by the thermodilution technique each value representing the mean of at least three consecutive measurements From the time of admission and during the whole CCU stay a continuous ECG was recorded and retained for visual evaluation

To provide an acute loading dose the first series of patients (Group 1) was given 0 [illegible] mg/kg/min tocainide as a continous infusion over 15 minutes The second series of patients (Group 2) received 0 75 mg/kg/min in the same way Hemodynamic measurements were performed immediately before as well as 15 30 45 and 60 minutes after the start of the tocainide infusion Thirty five minutes after termination of the infusion the patients randomly and double blindly received either two 400 mg tocainide tablets ([illegible] mg) or two placebo tablets Thereafter they received one tablet of either tocainide or placebo respectively every 8 hours for 24 hours Blood samples for tocainide analysis were collected from one of the catheters at 0 25 30 45 60 120 and 180 minutes after the start of the intravenous infusion as well as at 0 60 90 and 120 minutes

ell known[11] A total of 3 053 patients with myocardial infarction were studied 1 533 given practolol and 1 520 received a placebo duration of the study was 2 years There was erall reduction in the death rate including dden death rate of 38% The patients with ior myocardial infarction were reported to the most benefit although the reduction in n death rate was similar in the two groups ective of the site of the infarct

s study has been criticized on several ds such as it is not possible to assess the entativeness of patients with regard to or or inferior infarction without knowing mbers and reasons for exclusion from the and patients may have been selected as ed by the low total mortality rate The end of death and reinfarction were not clearly d if sudden death is the main end point it appear to be more important to discrimi ccording to blood pressure rather than to e of infarction Some workers have felt that sults presented did not warrant the conclu hat practolol is especially favorable in ts with a specific location of infarction Un able side effects from long term oral thera e now precluded the use of this agent

helmsson et al reported beneficial results prenolol in 230 patients subdivided into ent and placebo groups each stratified ne of four risk groups Group I had no ive cardiac damage Group II had mechan amage to the myocardium Group III had cal cardiac damage and Group IV was a nation of Groups II and III The dose of olol was 400 mg daily and the duration of al was 2 years Patients were entered 1 week hospital discharge After this time 11 ts in the placebo group and three in the ted group had died suddenly a small but cant fall in the sudden death rate resulted alprenolol therapy The mechanism of however is not clearly under —whether it is an antiarrhythmic effect or fect on myocardial metabolism Similar s have been reported by Ahlmark et al sing alprenolol The drug was given in a of 400 mg daily therapy being initiated 24 to 48 hours after the onset of infarction pected infarction The trial was continued year There was a significant reduction in ortality rate after 1 year in patients under 65 years of age There was no effect o th short term mortality rate It was not p ibl from the data presented to decide whether t e there was a significant drop in the sudden death rate although the results presented so ‹ (that practolol and alprenolol reduce the p farction mortality rate from sudden death

It is pertinent to ask whether the wide pr n use of beta blocker in all postmyocardial infarc tion patients is justified to achieve such a m ll percentage of benefit clinically If one assumes an annual postinfarction mortality rate of 6% and aims at achieving a 30% fall in the mortality rate with beta blocking therapy then only two out of every 100 patients would benefit Baber et al with the last point in mind carried out a long term trial in postinfarction patients using pro pranolol 40 mg daily designed on lines similar to the practolol trial their aim was to reduce the mortality rate by 50 c The trial failed to show a positive result

At present there are a number of long term trials being conducted throughout the world using various beta blockers such as acebutolol metoprolol oxprenolol pindolol propranolol sotalol and timolol (Table I) Whether these trials will answer certain questions posed by the practolol and alprenolol trials remains to be seen Certainly there has been no attempt in these trials to determine whether one beta blocker is superior to another Also none of these trials will define the mode of action of beta blockers in reducing the mortality rate Furthermore there does not appear to have been much attempt at stratifying patients to see what groups might benefit most from beta blocking therapy

Disopyramide

This drug has properties similar to those of quinidine and procainamide although its side effects are somewhat different because they are mainly confined to anticholinergic effects It has been shown to be as effective as quinidine in reducing ventricular ectopic activity but is claimed to have fewer side effects Comparative studies of disopyramide with atenolol mexilitine and placebo have been reported on a small num ber of patients but the duration of drug therapy was short 1 week for each drug No chronic comparative studies of disopyramide with other newer antiarrhythmic studies have been reported It is of interest however that Oshrain[1] has been

after the last oral dose at 24 hours Patients were questioned carefully to identify subjective symptoms and observed for objective signs of adverse effects The study code was broken after the hemodynamic antiarrhythmic and adverse effects had been evaluated in all patients

Results

Patient characteristics are shown in Table I There were no significant differences between Group 1 and Group 2 or between the tocainide and the placebo groups with respect to the variables described All patients were discharged from the hospital alive

Tocainide plasma concentrations Tocainide plasma concentrations for the two infusion rates are shown in Fig 1 At 15 minutes the mean plasma concentration for Group 1 patients receiving the 0 5 mg/kg/min dose was 43 8 ± 13 4 μmol/L For Group 2 patients receiving 0 75 mg/kg/min the 15 minute value was 63 6 ± 13 4 μmol/L The mean plasma concentration of the tocainide group at 24 hours immediately prior to the last oral dose was 26 6 ± 4 5 μmol/L

Hemodynamic measurements The mean and standard deviation of the hemodynamic measurements in all 18 patients are given in Table II At 15 minutes there was a small but significant increase in heart rate right atrial pressure pulmonary artery diastolic pressure aortic diastolic pressure and systemic vascular resistance There was also a small but significant decrease of cardiac index stroke index and left ventricular stroke work index Immediately before the tocainide infusion there were no statistically significant differences in any of the hemodynamic parameters between Group 1 and Group 2 patients At 15 30 45 and 60 minutes a significantly higher right atrial pressure was recorded in the Group 2 patients All other hemodynamic differences between the two groups were not statistically significant

The hemodynamic changes in the tocainide and placebo groups measured after the last oral dose at 24 hours are summarized in Tables III and IV At 0 minutes the time of the last dose there were no statistically significant differences between the tocainide and placebo groups with respect to

reported to have used disopyramide therapy in 59 patients for 5 years with suppression of ventricular ectopic beats (VEBs) and ventricular tachycardia (VT) in 60% of cases without development of serious side effects Its effect in preventing ventricular fibrillation (VF) was not reported in this series Jenning et al claimed that disopyramide was effective in a controlled myocardial infarction (MI) study in reducing the mortality rate (VF) compared with placebo This study, however has been criticized on several grounds The number of patients studied was small (30 treatment versus 30 placebo) the mortality rate in the placebo group was relatively high the selection of patients for treatment or placebo group was not clearly defined a high percentage of patients in the 70 to 80 years of age group appear to have been included and some patients on disopyramide did not appear to have any drug detectable in their plasma

Furthermore in spite of claims that disopyramide is safer than quinidine serious side effects have been reported Ross et al[2] have demonstrated profound hypotension after a single dose and potent depressive effect on A V node/bundle of His conduction Podrid et al have concluded that disopyramide exerts a profound negative inotropic effect that is unique among antiarrhythmic agents manifesting itself as congestive cardiac failure (CCF) This appears during the first 3 weeks of therapy but may require several months to develop They suggest that disopyramide is not indicated in patients with [illegible] ly or a past history of CCF This study therefore casts a cautionary note over the long term use of disopyramide

In a short term comparative study recently completed by Hampton et al (personal communication 1980) involving oxprenolol disopyramide and placebo in acute infarct patients followed up for 6 weeks the results are of some interest in view of the preceding comment (1) There was no significant difference in mortality rates between the three agents (2) disopyramide reduced the incidence of ventricular ectopics without affecting the death rate and (3) there was an excess of heart failure in those patients treated with disopyramide confirming the experience of Podrid et al[2]

Mexiletine and tocainide

Mexiletine is one of the newer antiarrhythmic drugs tested in recent years In several studies it has been compared with procainamide atenolol disopyramide and tolamolol but mostly on a short term basis There is good evidence from other studies that it is effective against VEB and VT[3] While the short term studies indicate that it is at least as effective as procainamide and disopyramide and more effective than atenolol and tolamolol (against ventricular arrhythmias) it has rather frequent side effects What its relative merits are on a long term basis has not yet been shown

Two other antiarrhythmic agents have been used and compared with placebo in long term studies—aprindine and tocainide The former drug was studied by Hagemeijer et al[4] It involved

any of the hemodynamic parameters In the tocainide group there was a small but statistically significant rise in the mean aortic pressure from 102 mm Hg at 0 minutes to 105 mm Hg at 90 minutes ($P < 0.05$) No other significant hemodynamic changes were observed In the placebo group there was an increase of heart rate from 81 beats/min at 0 minutes to [illegible] beats/min at 45 minutes (P [illegible]) and to [illegible] beats/min at 90 minutes ($P < 0.01$) The mean [illegible] pressure fell significantly from [illegible] mm Hg [illegible] minutes to 91 mm Hg at 90 minutes ([illegible]) No other significant hemodynamic [illegible] observed in this group No significant differences between the tocainide and the placebo groups were observed at 0 45 60 and 90 minutes with respect to any of the hemodynamic parameters

Antiarrhythmic effects Seven patients had ventricular tachycardia within 1 hour prior to the tocainide infusion compared to one patient during the 1 hour after the start of the infusion ($P < 0.05$) The corresponding figures for multifocal PVCs were nine and two patients respectively ($P < 0.05$) and for paired PVCs nine and three patients respectively ($P < 0.05$)

Within the nearest 15 minutes prior to the start

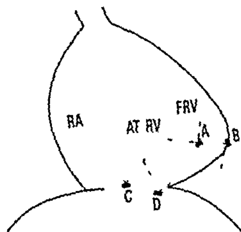

Fig 1 Position of the transducer and direction of the ultrasonic beam Position *A* provides an apical four-chamber view and position *B* shows a three chamber view of the right-sided heart from the apex which is nearly perpendicular to the cross section for the apical four chamber view Position *C* provides a horizontal subxiphoid cross-section and *D* indicates subxiphoid cross-section along the left costal margin

the STL in 10 normal subjects and in 10 patients with ASD of secundum type

b Three chamber view An apical three chamber view was obtained in nine of the 11 patients Fig 4 shows an example of the three chamber view in the same patient as Fig 2 A remarkable displacement of the STL is visualized whereas the ATL attaches to the original valve ring Moreover the tricuspid valve ring *(TVR)* is clearly visualized

Additionally the chordae tendineae inserting into the ATL were visualized in four instances from the four chamber view and in five cases from the three chamber view respectively

2 Subxiphoid cross-section We succeeded in recording the subxiphoid cross section in nine out of the 11 patients whereas in the remaining two the interpretable images could not be obtained due to liver enlargement or tight abdominal wall In order to obtain better images from this area we adjusted the gain setting by increasing the intensity of the ultrasonic beam and deepened the focal point

As a result the right sided heart chambers were widely observed as well as the interventricular septum and the left ventricle Moreover the elongated ATL was demonstrated clearly from the tip to the root attached to the tricuspid valve ring in eight out of the nine patients In addition the root of the ATL was remarkably thickened in five Fig 5 shows a subxiphoid cross section taken

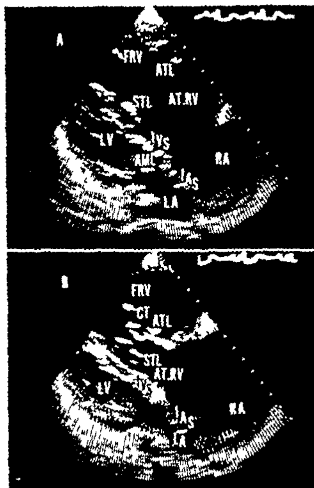

Fig 2 Four chamber view by cross section through the apex in a 3-year-old patient with Ebstein's anomaly *Top* diastolic picture *Bottom* systolic image The septal tricuspid leaflet is displaced downward into the right ventricle resulting in the formation of the atrialized and functional right ventricles *FRV* = functional right ventricle *AT RV* = atrialized right ventricle *RA* = right atrium *STL* = septal tricuspid leaflet *ATL* = anterior tricuspid leaflet IVS = interventricular septum IAS = interatrial septum *AML* = anterior mitral leaflet *LV* = left ventricle *LA* = left atrium *CT* = chordae tendineae

from the same patient as shown in Fig 2 The ATL is fully visualized from the tip to the root attached to the tricuspid valve ring The chordae tendineae *(CT)* inserting into the ATL are also discernible Fig 6 shows another example of the subxiphoid cross section in a 5 year old patient (F A) The ATL was fully described from the tip to the thickened root well as a part of the interventricular septum and the left ventricle In six patients the CT to the ATL was visualized in the subxiphoid cross section Moreover a hypertrophied anterolateral papillary muscle was also recognized in the subxiphoid cross section in one instance

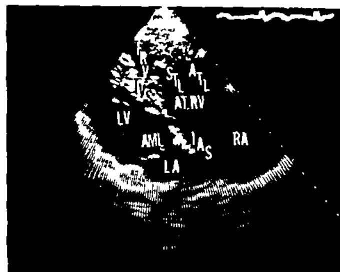

Fig 3 Another example of the four chamber view in a 21 year old female (A I) with Ebstein's anomaly and PFO The STL is displaced into the right ventricular cavity Abbreviations are the same as in *Fig 2*

Fig 5 Subxiphoid cross section taken from the same patient as in *Fig 2* The ATL is fully visualized from the tip to the root anchored on the right atrioventricular junction. The chordae tendineae *(CT)* inserting into the ATL are also discernible *CT* = chordae tendineae other abbreviations are the same as in *Fig 2*

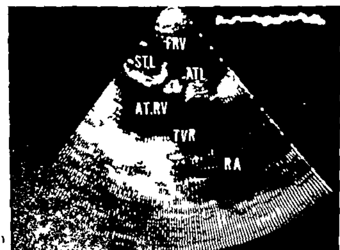

Fig 4 Three chamber view of the right sided heart by cross section through the apex in the same patient as in *Fig 2* The functional and atrialized right ventricles and the right atrium were depicted by cross section through the cardiac apex in direction *B* as shown in *Fig 1* Abbreviations are the same as in *Fig 2*

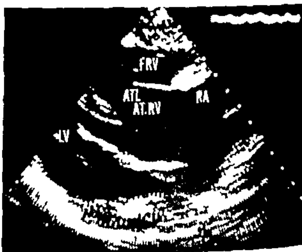

Fig 6 Another example of the subxiphoid cross section obtained from a 6 year old patient (F A) with Ebstein's anomaly associated with patent foramen ovale The elongated ATL is fully seen from the tip to the thickened root and the right side of the heart is widely visualized Abbreviations are the same as in *Fig 2*

In three patients the STL was found to be displaced downward by the subxiphoid approach

Discussion

Recently cross sectional echocardiography has come into clinical use thus providing useful information on cardiac anatomy and movements It is suitable for the spatial orientation of the heart structures because of its two dimensional nature

Matsumoto and associates[16] reported on the visualization of the tricuspid valve in Ebstein's anomaly using a mechanical sector scan However the probe was too large to be easily manipulated and the apical and subxiphoid approaches were not available Hirschklau and associates[7] applied a multicrystal echocardiographic system to this lesion to obtain real time observation of the tricuspid valve abnormalities However the scanner was not appropriate for the cross section through the subxiphoid area and the problem of

†$P < 0.01$

of the tocainide infusion four patients had more than five PVCs per minute. A reduction of the number of PVCs was seen in all four patients during 60 minutes following the start of the infusion. There were no statistically significant differences between the tocainide and placebo groups during the tablet administration period with respect to the incidence of ventricular tachycardia, multifocal PVCs, or paired PVCs. The number of PVCs in the tocainide group was significantly higher than the number in the placebo group during both the pretreatment period ($P < 0.01$) and the treatment period ($P < 0.001$). One patient in the placebo group (Case 7) developed ventricular fibrillation 4 hours after the start of the tocainide infusion (plasma concentration at this time 18.7 µmol/L).

Adverse effects. In association with the intravenous infusio[illegible] six patients, three in each group, had no adver[illegible] [illegible]cts at all. Eight patients, four in each grou[illegible] [illegible]rted a cool throat and a fresh taste of [illegible] mint, which was described as pleasant o[illegible] [illegible]npleasant, between 5 and 10 (mean 8 ± [illegible] after the start of the infusion. The d[illegible] [illegible]ned between 4 and 30 (mean 13 ± 8) m[illegible] [illegible] correlation was found between plasma [illegible] [illegible]ion of tocainide and side effects. Two p[illegible] [illegible]orted lightheadedness and two had on[illegible] [illegible] ode of vomiting 35 minutes after the start of the infusion. Three patients (Cases 3, 16, and 19) had bradycardia and hypotension 20, 25, and 35 minutes after the start of the tocainide infusion. They were easily treated by a head-down posture in two patients and atropine in the third patient with prompt disappearance of symptoms. No significant differences between the tocainide and placebo groups were observed during the long-term tablet administration period with respect to adverse effects (Table V).

Table V Adverse effects during the tocainide/placebo tablet period

Adverse effects	*Tocainide group*	*Placebo group*
No adverse effects	5	5
Nausea	1	1
Vomiting	1	2
Generalized warmth	0	1
Bradycardia and hypotension	1	0

Discussion

The new antiarrhythmic drug tocainide is effective against ventricular tachyarrhythmias when given both intravenously and orally. The effect seems to correlate with the concentration of drug in the plasma and a therapeutic range of 18 to 45

Tocainide for refractory ventricular arrhythmias of myocardial infarction

Charles I Haffajee M B Joseph S Alpert M D and James E Dalen M D *Worcester Mass*

Oral tocainide was used as a long term antiarrhythmic in patients with symptomatic high-grade ventricular ectopic activity refractory to conventional antiarrhythmic agents Eleven of the 22 patients had a previous myocardial infarction (three patients had a ventricular aneurysm) Unacceptable side effects precluded long term use of tocainide in two patients Long term tocainide was effective in six of the remaining patients for periods of 9 days to 42 5 months (mean 15 2 months) Eight of these nine patients responded to intravenous lidocaine prior to tocainide therapy

Chronic antiarrhythmic therapy with tocainide was evaluated in 22 patients with symptomatic high grade ventricular ectopic activity (10 with life threatening ventricular tachycardia) resulting from a variety of cardiac diseases The arrhythmias were refractory to all currently available antiarrhythmic agents in the United States both singly and in combination Eleven of the 22 patients had a previous myocardial infarction Unacceptable side effects precluded use of tocainide in two patients hence the experience in the remaining nine patients with previous cardiac infarction forms the basis of this report

Material and methods

Twenty two patients with refractory symptomatic high grade ventricular ectopic activity (VEA) including 10 patients with symptomatic ventricular tachycardia (VT) were considered for tocainide therapy Eleven of the 22 patients had a previous myocardial infarction and long term experience with nine of these patients forms the basis of this report (Table I) Three of these nine patients had a documented ventricular aneurysm and six of the nine patients had VT The ages of the nine patients ranged from 28 to 42 years (mean 54 years) eight patients were male Tocainide was employed chronically in these nine patients for 0 3 to 42 5 months (mean 25 5 months)

All nine patients had been previously treated with conventional antiarrhythmic agents available in the United States In the majority of the patients adequate plasma levels of these agents were achieved before their lack of efficacy was accepted The drugs were used singly and in combination or were considered to be contraindicated before tocainide therapy was instituted Of the agents used (Table II) quinidine was ineffective in all nine patients Procainamide was used in seven patients and found to be ineffective in five produced lupus erythematosus in two and was contraindicated in one patient Disopyramide was ineffective in two of the five patients in whom it was used and had to be discontinued because of unacceptable side effects in the remaining three (60%) patients Disopyramide was contraindicated in three patients and not commercially available for use in one patient Propranolol was ineffective in five of the nine patients in whom it could be used

Oral tocainide was begun after discontinuation of all previous antiarrhythmic agents with the exception of lidocaine It was initially employed at 400 mg every 6 to 8 hours and more recently at a dose of 600 mg every 8 to 12 hours The dosage was increased every 24 to 48 hours until acceptable arrhythmia control or unacceptable side

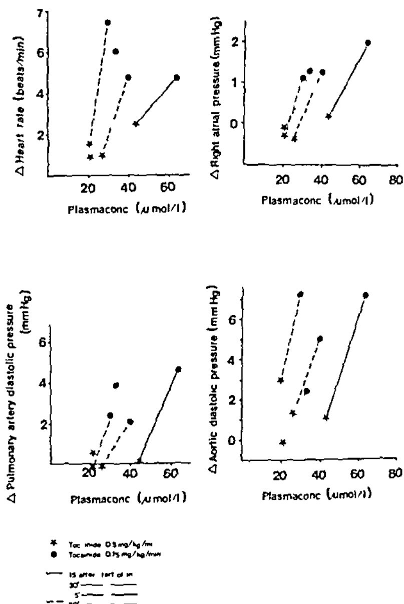

Fig 2 Changes in heart rate right atrial mean pressure pulmonary artery diastolic pressure and aortic diastolic pressure in relation to plasma concentration of tocainide and two infusion rates

μmol/L has been suggested In the present study only one of the Group 1 patients was slightly below the recommended therapeutic interval during the 45 minutes after the tocainide infusion On the other hand five of the Group 2 patients had plasma concentrations rather high above the suggested therapeutic range at 15 minutes after the start of the infusion Until the therapeutic range has been definitely settled the data from the present investigation suggest that an infusion rate of 0 ,0 mg/kg/min may be sufficient in patients with AMI Plasma conc ... trations were well within the suggested therap ... range with the dosage regimen of ... followed by 400 mg t i d used in the ...

The patients participating in the present study all had AMI with onset of symptoms with n 24 hours prior to the tocainide infusion Some of the patients had considerable left ventricular dysfunction cardiac indices varying between 1 7 and 3 1 L/min/m² pulmonary artery diastolic pressures varying between 4 and 20 mm Hg and/or right ventricular failure with mean right atrial pressures varying between 0 and 11 mm Hg Intravenous tocainide was well tolerated hemodynamically by all patients but three Although statistically significant the hemodynamic changes were small In all 18 patients the mean change at 15 minutes was an increase in heart rate of 3 beats/min (4%) in mean right atrial

Propranolol	5	[illegible]	4	0
Phenytoin	3	3	0	0

effects intervened After 48 hours of therapy an absorption distribution tocainide curve was obtained in every patient and thereafter trough levels were used as a guide to therapeutic effectiveness Peak levels which are achieved 60 to 90 minutes after the drug is taken were obtained if side effects occurred The daily tocainide dose ranged from 1,200 to 3 200 mg/day (mean 1 900 mg/day) in the nine patients

Prior to oral tocainide therapy ventricular arrhythmias in all nine patients were documented during ambulatory coronary care unit or telemetry ECG monitoring. Subsequent short term (computerized arrhythmia detection system) and long term ECG ambulatory (Holter) monitoring was conducted at frequent intervals during tocainide therapy In addition treadmill exercise testing (Bruce protocol) was employed in two patients in whom exercise testing had induced VEA/VT

Ventricular arrhythmias were assessed by hourly counts of VEA and occurrence of couplets and VT during frequent outpatient ambulatory ECG monitoring A reduction in VEA and elimination of couplets and/or VT was sought during treadmill exercise testing in the two patients with exercise induced VEA/VT

Symptoms caused by VEA/VT were also monitored in all patients during oral tocainide therapy Side effects were monitored through spontaneous comments and direct questioning at each visit Prior to institution of tocainide therapy baseline ECGs chest x ray films antinuclear antibody (ANA) titers Coombs test and hematologic hepatic and renal function were assessed In addition urinalysis and ophthalmologic assessment were performed on all the patients At periodic intervals throughout the duration of therapy these tests were repeated

Results

Results are shown in Table I

Arrhythmias In three of five patients with VT there was either abolition or marked reduction in episodes of VT while they were on tocainide as assessed by 24 hour ambulatory monitoring (two patients) and by exercise testing (one patient)

In five of the nine patients there was a significant reduction in total hourly VEA count ([illegible] VEA/hr before and 44 VEA/hr during tocainide therapy $P < 0.05$ Student's t test) However in the group as a whole the mean hourly VEA before tocainide therapy was 362 ± 347 whereas during tocainide therapy it was 9[illegible] ± [illegible] ($P = 0.08$ Student's t test) In one patient there was an increase in mean hourly VEA count (13 to 60) When the Lown system of grading VEA was used for analysis there was an improvement in Lown grade of VEA in six of the nine patients All nine patients were in Lown grade 4A or 4B prior to tocainide therapy Three patients improved

pressure of 1 mm Hg (25%) in pulmonary artery diastolic pressure of 2 mm Hg (19%) in aortic diastolic pressure of 4 mm Hg (5%) and in systemic vascular resistance of 2 units (10%), there was a decrease in cardiac index of 0 2 L/min/m² (6%) and in stroke index of 3 ml/m At 30 and 45 minutes there was a gradual return toward control values Although correlated to the tocainide plasma concentrations the hemodynamic changes seemed to be more dependent upon the tocainide infusion rate as shown in Fig 2 During the tablet administration period no significant differences were observed at any time between the tocainide and placebo groups with respect to any of the hemodynamic variables measured

Although some of the arrhythmias in the present study may have been artificially caused by the catheters a significant antiarrhythmic effect was seen during 1 hour after the tocainide infusion regarding ventricular tachycardia and multifocal and paired PVCs In the four patients who had more than five PVCs per minute a reduction of the number of PVCs was seen in all During the tocainide/placebo tablet period no significant difference was observed between the tocainide and placebo groups with respect to the incidence of ventricular arrhythmias Most patients had minor side effects of little clinical importance However three patients after the infusion had sudden onset of bradycardia and hypotension which were easily and rapidly treated

Summary

The hemodynamic and antiarrhythmic effects were evaluated after tocainide was given intravenously over a 15 minute period to 18 patients with AMI within 24 hours after onset of symptoms Doses were 0 5 (nine patients) and 0 75 (nine patients) mg/kg/min Tocainide infusion produced small but statistically significant increases in heart rate mean right atrial pressure pulmonary artery diastolic pressure aortic diastolic pressure and systemic vascular resistance It also caused small but significant decreases in cardiac index stroke index and left ventricular stroke index Although correlated to the tocainide plasma concentrations the hemodynamic changes seemed to be more dependent upon the tocainide infusion rate The data from the present investigation suggest that an infusion rate of 0 50 mg/kg/min may be sufficient in patients with AMI Ventricular tachycardia and multifocal and paired PVCs were significantly reduced after tocainide infusion Most patients had side effects but these were mild and transient After the tocainide infusion however three patients had an episode of bradycardia and hypotension which were easily and rapidly treated in all patients

After the infusion the patients randomly and double blindly received either two 400 mg tocainide tablets or two placebo tablets and thereafter one tablet of either tocainide or placebo respectively every 8 hours for 24 hours This resulted in plasma concentrations within the suggested therapeutic range no significant hemodynamic changes and minor side effects These findings suggest that oral tocainide can be used safely for antiarrhythmic therapy in patients with AMI

from Grade 4 to 1 two patients from Grade 4 to 3 and one patient from Grade 4 to 2 (Table I Fig 1) Three of five patients noted considerable improvement in palpitations

Pharmacokinetics The peak plasma tocainide levels in the nine patients ranged from 8 7 to 15 1 μg/ml (mean 10 6 μg/ml) The trough tocainide levels ranged from 1 4 to 7 5 μg/ml (mean 5 0 μg/ml) Higher trough (6 7 versus 4 0 μg/ml) and peak (12 7 versus 9 4 μg/ml) levels of tocainide were achieved in nonresponders compared to responders

Side effects Transient central nervous system (CNS) symptoms occurred in seven of the nine patients (77%) at some early point during tocainide therapy The most common symptoms were paresthesias (3 patients) ataxia (4 patients) blurring of vision (2 patients) and slurred speech (4 patients) Severe CNS side effects occurred in two patients on day 1 and day 3 of therapy (confusion and paranoia in one patient ataxia of gait and speech in the other) and precluded long term use of tocainide in these patients

Minor gastrointestinal side effects (nausea anorexia and vomiting) occurred transiently in six of the nine patients However both the gastrointestinal and CNS side effects were overcome in all nine patients by reduction of dosage or taking the drug with food

ANA titers were slightly elevated in three patients during tocainide therapy In one patient who previously developed procainamide induced lupus the ANA titers were markedly elevated prior to tocainide therapy In this individual ANA titers fell during tocainide therapy In two other patients minimally elevated ANA titers developed during long term tocainide therapy However neither of these patients has developed clinical evidence of lupus as yet The patient with procainamide induced lupus developed a skin rash on chronic tocainide therapy that did not recur on reinstitution of tocainide after initial withdrawal

No systemic (hepatic renal hematologic and ophthalmologic) abnormalities were detected during periodic blood tests during chronic tocainide therapy No significant ECG conduction abnormalities were detected during chronic tocainide therapy

Intravenous lidocaine responsiveness in the prediction of tocainide efficacy Intravenous lidocaine was used in eight of the nine patients for suppression of VT/VEA prior to tocainide therapy Long term oral tocainide was effective in six of the eight lidocaine responders (75%)

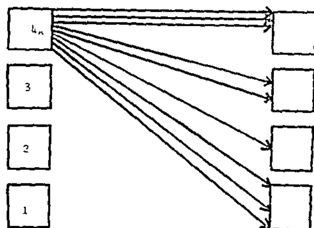

Fig 1 Improvement in Lown grade during tocainide therapy

Patients dying while on long term tocainide therapy Two patients died while on chronic tocainide therapy One of the two patients died from refractory cardiac failure 21 days following an extensive myocardial infarction and the second patient died from chronic congestive cardiac failure Neither of these deaths appeared to be related to tocainide therapy

Withdrawal of tocainide therapy Tocainide withdrawal was attempted in two responders after 28 and 19 months of chronic therapy respectively In both patients there was a prompt return of VEA during ambulatory monitoring in the first month following discontinuation of therapy No withdrawal was attempted in the three patients with VT who responded to and were on long term tocainide therapy

Discussion

Tocainide was effective in six of the nine (66%) patients for periods from 9 days to 42 5 months (mean 15 2 months) Four (41%) of these patients are still on maintenance tocainide therapy for periods of 3 5 to 42 5 months (mean 25 5 months) Three of the nine patients had a ventricular aneurysm and tocainide was effective in only one of these three patients In the majority of patients the drug was given every 8 hours and dosages ranged from 1,200 to 3 200 mg/day (mean 1,900 mg/day)

Minor side effects early on in therapy were

Prophylaxis of ventricular tachyarrhythmias with intravenous and oral tocainide in patients with and recovering from acute myocardial infarction

Lars Rydén, M.D., Krister Arnman, M.D., Thor Bjorn Conradson, M.D., Stefan Hofvendahl, M.D., Ole Mortensen, M.D., and Peter Smedgard, M.D.
Skövde and Helsingborg, Sweden

In a double-blind placebo controlled study, tocainide 750 mg i.v. during a 15 minute period directly followed by 800 mg orally and later 400 mg t.i.d. was administered to patients with acute myocardial infarction (AMI). Treatment was started as soon as possible following onset of symptoms; the follow-up period was 6 months. The patient groups consisted of 56 tocainide and 56 placebo patients. There was no significant effect on the incidence of ventricular fibrillation or symptomatic ventricular tachycardia. The mortality rates were similar and low in both groups. Tocainide suppressed ventricular arrhythmias including ventricular tachycardia, both in the acute stage of AMI and during convalescence. Tocainide also suppressed exercise induced ventricular arrhythmias. Side effects were in general mild or moderate.

Tocainide is an important new membrane active antiarrhythmic agent which we have evaluated in patients after myocardial infarction. The primary aim of this study was to assess the ability of tocainide to prevent ventricular fibrillation (VF), symptomatic ventricular tachycardia (VT), and sudden death in patients with acute myocardial infarction (AMI). Secondary aims were to assess the activity of tocainide against less serious spontaneous and exercise induced arrhythmias such as short runs of VT and ventricular premature complexes (VPCs) and to study the safety of intravenous and oral tocainide when given to patients with and recovering from AMI.

Material and methods

Patients. The patients enrolled in the study were all admitted to the coronary care units (CCUs) of the Central Hospitals of Skövde and Helsingborg, Sweden, during the period from June 1978 to May 1979. All patients less than 71 years old admitted with symptoms suggestive of AMI within the previous 48 hours were considered for inclusion. Indications for exclusion are summarized in Fig. 1.

Patients suitable for inclusion were then randomly treated with either tocainide or matching placebo. The dose of tocainide was 750 mg i.v. given by continuous infusion over a 15 minute period, 800 mg orally given at the end of the infusion, and 400 mg orally given every 8 hours starting 8 hours later. Patients in the placebo group received intravenous saline solution followed by lactose tablets in an identical regimen. Treatment with oral medication was then continued double blind for a period of 6 months after the initial admission. Patients were withdrawn from the study if the diagnosis of AMI was not confirmed or if they developed defined exclusion criteria (Fig. 1).

Assessment procedures. All patients included in the study were subject to standard CCU surveillance and treatment, and following discharge they were assessed clinically at 1, 3, and 6 months.

Continous ECG recordings were made by means of an Oxford instrument recorder for the first 24 hours in the hospital, on day 10 (before discharge) and at Skövde 1 and 6 months after

experienced by the majority of patients (9 of 12 75%) However side effects were transient and overcome gradually by taking the drug with food or by dosage reduction Side effects precluded long term therapy with tocainide in 2 of the 11 (18%) patients

Intravenous lidocaine was effective in eight of the nine patients with myocardial infarction Oral tocainide subsequently proved to be effective long term in six (75%) of these lidocaine responders

No adverse conduction abnormalities were detected during this study However none of the patients underwent intracardiac electrophysiology before or during tocainide therapy Moore et al[2] have characterized the electrophysiologic safety of tocainide in man

The effectiveness of tocainide in suppressing VEA VT in man has previously been demonstrated in short term studies by Winkle et al [3] Woosley et al and Ryan et al [5] and in long term studies by Winkle et al [6] and Engler et al [7] However in both of these long term studies [7] disopyramide was not employed prior to tocainide therapy Moreover other antiarrhythmic medications were continued in their patients while on tocainide therapy

We recognize the limitations of 24 hour and short term ambulatory ECG monitoring [8] the Lown grading system the lack of a single accurate and reproducible standard for monitoring arrhythmias and the lack of intracardiac VT initiation by pacing during tocainide therapy in our patients However it appeared that in our highly symptomatic group of patients with VEA/VT resulting from chronic coronary artery disease both symptomatic episodes of VT and VEA counts and complex forms decreased during tocainide therapy

Tocainide appears to be a promising and useful addition to our limited armamentarium of antiarrhythmic agents It would appear to be a logical choice for chronic therapy in those patients in whom lidocaine results in VEA/VT suppression An acceptable level of side effects was noted early in therapy and no long term sequelae resulted from tocainide therapy in our patients

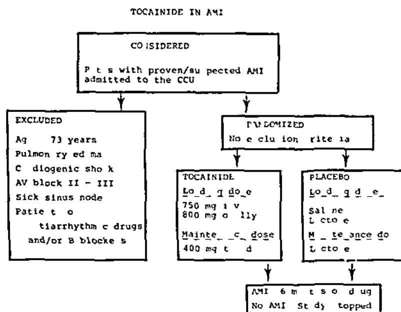

Fig 1 Study design

discharge The patients from Skovde also had ECGs recorded during exercise testing on a bicy cle ergometer conducted 1 3 and 6 months after discharge

Exercise tests were performed on an electrically braked bicycle ergometer (Siemens Elema Swe den) under standardized conditions The ECG was recorded at each work load reached and repeatedly during the first 10 minutes after exer cise The initial work load was usually 30 watts for women and 50 watts for men which was then increased stepwise by 10 watts/min For the exercise test 1 month following AMI patients exercised either until definite symptoms occurred or until the increase in heart rate or other obser vations was such that it was thought prudent to stop For the exercise tests at 3 and 6 months all patients were exercised until symptoms such as angina pectoris dyspnea and tiredness made it impossible to continue work serious ventricular tachyarrhythmias occurred (VT or numerous VPCs with hemodynamic deterioration) or a combination of these problems was noted Thus the work load at 3 and 6 months may be consid ered maximal

All 24 hour tapes were analyzed both by the use of a Pathfinder Arrhythmia Computer and by eye following operator controlled printout of sus picious events The number of hours containing no arrhythmias infrequent (< 30/hr) or frequent (> 30/hr) VPCs or VT (rate > 100 three or more consecutive beats) and the number of patients with these arrhythmias in any assess ment period was used for comparisons between the groups

Exercise induced ventricular tachyarrhyth mias reported are arrhythmias occurring either during or directly following the exercise test and disappearing spontaneously with continued rest

These VPCs have been classified as monofocal multifocal and paired and their frequency esti mated at the time of occurrence

Results

A total of 162 patients who fulfilled entry criteria were enrolled in the study One other patient entered 55 hours after the onset of symp toms was excluded from the overall analysis One hundred and twelve patients were diagnosed as having AMI by WHO criteria and of these 56 were given tocainide and 56 placebo In 50 patients the diagnosis of AMI could not be sus tained Twenty six of these patients received tocainide and 24 placebo

Because of technical difficulties it was not possible to analyze the tape recordings made in one of the centers (Helsingborg) Spontaneous ventricular arrhythmias not resulting in with drawal from the study therefore are reported only for the patients enrolled at Skovde Technical problems resulted in the loss of only a few tapes (~ 6%) and full 24 hour recordings were obtained

III Chronic tocainide therapy studies

A prospective randomized trial of tocainide in patients following myocardial infarction

B C Bastian M B Ch B, P W Macfarlane B Sc Ph D J H McLauchlan M B Ch B D Ballantyne, M D R Clark M B Ch B W S Hillis M B Ch B A P Rae B Sc M B and I Hutton M D *Glasgow, Scotland*

One hundred forty six patients with recent acute myocardial infarction were grouped at random into those treated with tocainide an oral analogue of lignocaine or placebo and followed up for 6 months In addition to standard investigations a 24-hour ambulatory taped ECG recording was obtained prior to randomization and thereafter at 2 8 16 and 24 hours after discharge The ECGs were analyzed by means of an automated computerized reporting system Forty two patients had significant ventricular arrhythmias 10 of whom had effective plasma levels of tocainide compared with 27 patients on placebo ($P < 0.005$) In the placebo patients with increasing mobilization there was a consistent rise in the number of ventricular ectopic beats per day There was no such increase in the tocainide patients ($P < 0.01$) Side effects were few and the incidence of central nervous system side effects was similar in both the tocainide and placebo groups There was no conclusive evidence of myocardial depression heart rate and blood pressure being unchanged over the 6 month period Although ventricular arrhythmias were suppressed the number of patients in the study was too small to draw conclusions regarding the mortality rate

The risk of sudden death is increased in patients with coronary heart disease particularly in patients with ventricular ectopic beats[1-4] It therefore seems reasonable to try and prevent such ventricular arrhythmias Tocainide is an analogue of lignocaine and has been shown to be an effective antiarrhythmic agent in animals and in several preliminary studies in patients It is almost 100% absorbed after oral administration and has a plasma half life of approximately 12 hours in patients with normal renal and hepatic function[11,12] The purpose of the present study was to evaluate the effects of tocainide on the prevention of ventricular arrhythmias in a placebo controlled trial in patients recovering from an acute myocardial infarction and followed up for a 6-month period A further objective was to determine the incidence of side effects related to long term tocainide therapy

MATERIAL AND METHODS

The patient population was drawn from three hospitals in Glasgow Scotland (Dr D Ballantyne Victoria Infirmary and Dr W S Hillis Stobhill Hospital) The coordinating center was situated in the University Department of Medical Cardiology The Royal Infirmary Glasgow (Dr Ian Hutton) A total of 146 patients under the age of 70 years were entered into the trial There were 121 men and 25 women with an average age of 55 years The two groups were well matched with respect to age site of infarction and estimated size of infarction from enzyme studies as can be seen in Table I The diagnosis of acute myocardial infarction was confirmed clinically and by ECG changes—pathologic Q waves and sequential ST T wave changes and by elevation of the serum enzymes serum glutamic oxaloacetic transaminase (SGOT) lactic dehydrogenase (LDH) and creatine phosphokinase (CPK)

Exclusion criteria were as follows (1) abnormal renal or hepatic function (2) Grade II or III A V block (3) persisting ventricular arrhythmias requiring treatment, (4) continued treatment

in over 97 of the tapes available in this group These losses and the patient withdrawals account for the varying numbers of patients included in the arrhythmia analysis at different times Contraindications to exercise testing in some patients contributed to a similar variation in the numbers of patients tested

There were no significant differences between the groups in terms of sex distribution age past history previous treatment dela from onset of symptoms t in lu ion and ite of infarct The maximum S AS AT level h w er was significantly higher in the gr up i en tocainide (4.11 ± 2.78 µk t L comp ... 2.97 ± 2.17 $P < 0.05$ Table I

Ten patients gi n toc ai ... io given placebo were withdrawn at varying times during the first days of the study some (nine) according to the protocol and some (11) because of their refusal to participate in the 6 month follow up phase of the study Their withdrawal did not influence the comparability of the two treatment groups Data derived from all patients withdrawn from the study are included in the appropriate analyses up to the time of withdrawal

Deaths The mortality rate of the two groups was similar and the overall mortality in the study was low (8.7%) The mortality remained low (11.7%) when two patients who died after withdrawal from the study (one tocainide patient with aplastic anaemia one placebo patient with VF) were included in the analysis

Except for the patient with aplastic anemia none of the causes of death was unusual or unexpected in view of the primary diagnosis and none was unequivocally due to the administration of tocainide or the study design

experienced by the majority of patients (9 of 12, 75%). However, side effects were transient and overcome gradually by taking the drug with food or by dosage reduction. Side effects precluded long term therapy with tocainide in 2 of the 11 (18%) patients.

Intravenous lidocaine was effective in eight of the nine patients with *myocardial infarction*. Oral tocainide subsequently proved to be effective long term in six (75%) of these lidocaine responders.

No *adverse* conduction abnormalities were detected during this study. However, *none of the* patients underwent *intracardiac* electrophysiology before or during tocainide therapy. Moore et al.[2] have characterized the electrophysiologic activity of tocainide in man.

The effectiveness of tocainide in suppressing VEA/VT in *man* has previously been demonstrated in short term studies by Winkle et al.,[3] Woosley et al.,[4] and Ryan et al.[5] and in long term studies by Winkle et al.[6] and Engler et al.[7] However, in both of these long term studies[6,7] disopyramide was not employed prior to tocainide therapy. Moreover, other antiarrhythmic medications were continued in their patients while on tocainide therapy.

We *recognize* the limitations of 24 hour and *short term* ambulatory ECG *monitoring*,[8] the Lown grading system,[9] the lack of a single accurate and reproducible standard for monitoring arrhythmias, and the lack of intracardiac VT initiation by pacing during tocainide therapy in our patients. However, it appeared that in our highly symptomatic group of patients with VEA/VT resulting from chronic coronary artery disease, both symptomatic episodes of VT and VEA counts and complex forms *decreased* during tocainide therapy.

Tocainide appears to be a promising and useful addition to our limited armamentarium of antiarrhythmic agents. It would appear to be a logical choice for chronic therapy in those patients in whom lidocaine results in VEA/VT suppression. An acceptable level of side effects was noted early in therapy and no long term sequelae resulted from tocainide therapy in our patients.

101	0	0	0
105	Monofocal paired ~10/min	0	0

Withdrawals Twenty two patients given tocainide and 13 given placebo were withdrawn from the study because of failure of therapy or potential side effects The difference between the groups was primarily attributable to the greater number of patients withdrawn from tocainide because of side effects (nine compared to two) The number of patients withdrawn because of VT asystole or A V block was essentially the same in both groups (Table II)

Five patients in the tocainide group developed *significant* VT One patient developed rapid VT 4 minutes after the start of the tocainide infusion and consequently had only a very low plasma level when withdrawn Therefore the failure of tocainide therapy in this patient is questionable However the bursts of VT that were noted before the injection deteriorated into sustained rapid VT after tocainide Although this is often the natural history of this arrhythmia it is possible that the low concentration of tocainide produced a more rapid reentry circuit than was possible in the absence of the drug Although the patient did not respond to procainamide he did respond to disopyramide

Two patients developed VF 4 5 hours and 11 days respectively after inclusion in the study Plasma tocainide concentrations were low in both cases Lidocaine was ineffective in both patients and the arrhythmias responded to procainamide One patient developed VF despite having a plasma tocainide concentration in the middle of the suggested therapeutic range This patient s arrhythmia was also refractory to lidocaine but responded to procainamide One patient developed sustained VT at a rate of 180/min despite a therapeutic plasma tocainide concentration The arrhythmia was also refractory to quinidine and procainamide Since it was possible to terminate the arrhythmia repeatedly with intravenous lidocaine the patient was again given tocainide but an increased dosage This successfully controlled the arrhythmia

Spontaneous VTs observed on continuous ECG recordings Over the first 24 hours continuous ECG recordings were obtained from 31 tocainide and 34 placebo treated patients The total number of recorded hours was 1 291 The tocainide treated patients had significantly fewer recorded hours containing VPCs than did the

III Chronic tocainide therapy studies

A prospective randomized trial of tocainide in patients following myocardial infarction

B C Bastian M B, Ch B P W Macfarlane B Sc Ph D J H McLauchlan M B Ch B D Ballantyne M D R Clark M B Ch.B W S Hillis M B Ch B A P Rae B Sc M B and I Hutton M D Glasgow Scotland

One hundred forty six patients with recent acute myocardial infarction were grouped at random into those treated with tocainide an oral analogue of lignoca ne or placebo and followed up for 6 months In addition to standard investigations a 24-hour ambulatory taped ECG recording was obtained prior to randomization and thereafter at 2 8 16 and 24 hours after discharge The ECGs were analyzed by means of an automated computerized reporting system Forty two patients had significant ventricular arrhythmias 10 of whom had effect ve plasma levels of toca nide compared with 27 patients on placebo ($P < 0\ 005$) In the placebo patients with increasing mobilization there was a consistent rise in the number of ventricular ectopic beats per day There was no such increase in the tocainide patients ($P < 0\ 01$) S de effects were few and the incidence of central nervous system s de effects was s milar in both the tocainide and placebo groups There was no conclusive evidence of myocardial depression heart rate and blood pressure being unchanged over the 6 month period Although ventricular arrhythmias were suppressed the number of patients in the study was too small to draw conclus ons regard ng the mortality rate

The risk of sudden death is increased in patients with coronary heart disease particularly in patients with ventricular ectopic beats It therefore seems reasonable to try and prevent such ventricular arrhythmias Tocainide is an analogue of lignocaine and has been shown to be an effective antiarrhythmic agent in animals and in several preliminary studies in patients[6-9] It is almost 100% absorbed after oral administration and has a plasma half life of approximately 12 hours in patients with normal renal and hepatic function[11,12] The purpose of the present study was to evaluate the effects of tocainide on the prevention of ventricular arrhythmias in a placebo controlled trial in patients recovering from an acute myocardial infarction and followed up for a 6-month period A further objective was to determine the incidence of side effects related to long term tocainide therapy

MATERIAL AND METHODS

The patient population was drawn from three hospitals in Glasgow Scotland (Dr D Ballantyne Victoria Infirmary and Dr W S Hillis Stobhill Hospital) The coordinating center was situated in the University Department of Medical Cardiology The Royal Infirmary Glasgow (Dr Ian Hutton) A total of 146 patients under the age of 70 years were entered into the trial There were 121 men and 25 women with an average age of 55 years The two groups were well matched with respect to age site of infarction and estimated size of infarction from enzyme studies as can be seen in Table I The diagnosis of acute myocardial infarction was confirmed clinically and by ECG changes--pathologic Q waves and sequential ST T wave changes and by elevation of the serum enzymes serum glutamic oxaloacetic transaminase (SGOT) lactic dehydrogenase (LDH) and creatine phosphokinase (CPK)

Exclusion criteria were as follows (1) abnormal renal or hepatic function (2) Grade II or III A V block (3) persisting ventricular arrhythmias requiring treatment (4) continued treatment

placebo treated patients Frequent VPCs and/or VTs on any occasion during the first 24 hours occurred in 19% of tocainide treated patients and in [illegible] of those given placebo This difference is statistically significant ($P < 0.05$) The percentage of patients with VT was significantly greater in the placebo group (41% compared to 13% $P < 0.05$)

One and six months after inclusion in the study fewer patients in the tocainide group had VTs but because of the small number of observations this difference did not reach statistical significance (Table III) Notwithstanding this the number of hours during which arrhythmias occurred was significantly less in the tocainide group at all assessment times except at 10 days

Exercise induced ventricular arrhythmias There were no significant differences between the maximum workloads achieved by the two groups at any observation period nor between the heart rates and systolic blood pressures In general the reasons for discontinuation of exercise were similar in the two groups The development of VTs however resulted in discontinuation of the exercise test in three patients given placebo on four occasions while in the tocainide [illegible] exercise tests were discontinued be[illegible] development of such arrhythmias

More patients in the placebo group developed VTs on exercise (Tables IV and V) Although the difference between the groups did not reach statistical significance at 1 and 3 months after AMI the incidence of arrhythmic events in the placebo group was significantly greater at the 6 month exercise test ($P < 0.05$) A significantly greater number of patients in the placebo group had exercise arrhythmias on one or more occasions (13 compared to two $P < 0.01$) Since VT did not occur after exercise in tocainide treated patients, the data suggest that tocainide was associated with a reduced incidence of serious ventricular arrhythmias in these patients The greater number of patients with frequent paired and/or multifocal VPCs induced by exercise in the placebo group also supports this conclusion

Tolerability No clinically important changes in mean blood pressure or heart rate occurred within the 60 minute period following the injection of tocainide There were no significant differences in mean blood pressure and heart rate between the tocainide and placebo treated groups 10 days 1 month 3 months and 6 months after the start of treatment Side effects following intravenous injection were more common in the tocainide treated patients (n = 17) than in those receiving placebo (n = 3)

CNS symptoms were the most common side effects seen in the tocainide group and usually consisted of paresthesias described as a numbness in the throat tingling sensations in the lips a feeling of cold or warmth and in a few cases a tingling sensation in the arms CNS side effects were all reported as mild or moderate except in one patient who developed confusion 5 minutes after the start of tocainide injection (250 mg) The infusion was stopped and the patient was withdrawn from the study The symptoms disappeared completely 10 to 15 minutes after the injection was terminated

Gastrointestinal complaints were the next most common side effects in patients given tocainide These usually included mild to moderate nausea followed by vomiting

Cardiovascular side effects occurred in four patients in association with intravenous tocainide administration and consisted of a fall in blood pressure and heart rate The injection was completed when the blood pressure stabilized following atropine and/or a short break in the infusion

Withdrawals due to side effects Nine patients

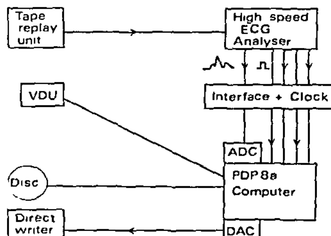

Fig 1 The tape replay computer analysis system ADC = analogue digital convertor DAC = digital analogue convertor VDU = visual display unit

with β adrenergic receptor blocking drugs and (5) persisting angina pectoris

Patients were considered for entry into the study 7 to 10 days after hospital admission for acute myocardial infarction The use of cardiac glycosides and diuretics was not considered a contraindication A detailed history was obtained and physical examination performed A 12 lead ECG and chest x ray film were taken Blood was taken for standard hematologic and biochemical screening for hepatic and renal abnormalities and an antinuclear antibody (ANA) titer A 24 hour taped ECG was recorded at a time when the patient was ambulatory prior to hospital discharge Written consent was obtained from the patient and either tocainide 200 mg t i d or placebo was given in a randomized double blind fashion The patients were reviewed as outpatients at 2 8 16 and 24 weeks after discharge and again at 25 weeks when medication had been discontinued

The preceding investigations including ANA and 24 hour ECG recording were repeated at each outpatient visit In addition information regarding possible adverse events was carefully collected at each clinic visit Blood was taken for plasma tocainide levels approximately 2 to 3 hours after administration of the medication

Patients were withdrawn from the study if treatment failed i e if significant ventricular arrhythmias developed ' and if an adverse event occurred such as left heart failure angina pectoris requiring the use of β adrenergic receptor blocking drugs or side effects of such severity as to be unacceptable to the patient developed

Twenty four-hour ECG analysis ECGs were taped by means of Oxford Medical Instruments Medilog 24 hour recorders The Oxford tape unit was linked to a high speed ECG analyzer (Pathfinder) of Reynolds Medical Electronics A technician teaches the analyzer the morphology of the normal QRS complex and analysis thereafter is automatic once the appropriate triggering levels have been set The outputs from the high speed analyzer are interfaced to a PDP8A minicomputer (Fig 1) The particular outputs utilized are the logic pulse which indicates whether a QRS complex is normal or abnormal In addition the ECG signal itself is fed from the replay unit to the computer

The interface has been designed to lengthen the logic pulse which indicated the morphology of the QRS complex It also filters the ECG signal to remove high frequency noise In addition it contains a clock used to control analogue to digital conversion of the ECG signal at a rate equivalent to 125 samples/sec real time Arrhythmic events can be detected and automatically printed by the Pathfinder and/or by the computer The printout from the computer provides a breakdown of the 24 hour recording into 15 minute periods for which the average heart rate and frequency of ventricular ectopic beats supraventricular tachycardia and ventricular tachycardia are produced Thus the system automatically captures arrhythmic events produces an interpretation and outputs the relevant ECG strip[13]

The accuracy of the reporting system is dependent on the Reynolds Pathfinder and this has been reported in a number of studies[14] The sensitivity of the method will depend on the population studied and for the identification of the aberrant beats the sensitivity is in the order

total were withdrawn from the tocainide study because of side effects One patient suffered nausea and vomiting two developed rashes five had different types of CNS side effects and one developed aplastic anemia The gastrointestinal and in three cases the CNS side effects were finally considered to be caused by tocainide as were the rashes

In one patient aplastic anemia was diagnosed 36 days after the start of treatment with tocainide This patient had serious AMI resulting in congestive cardiac failure which was treated with furosemide spironolactone digoxin and prazosin The patient was readmitted with septicemia secondary to agranulocytosis Tocainide and prazosin were withdrawn and the patient died of VF following the development of cardiogenic shock within 24 hours of admission The etiology of the aplastic anemia is not known but tocainide furosemide spironolactone and prazosin could be implicated as a cause of the aplastic anemia and agranulocytosis although it is not possible to determine whether any of these agents singly or in combination were cause and effect related

Plasma tocainide concentrations The mean and individual plasma tocainide concentrations obtained in a random sample of patients from both treatment centers showed that the dosage regime produced mean plasma concentrations within the suggested therapeutic range (18 to 45 μmol/L) at all sampling times

During the 6 month follow up period the vast majority of patients had tocainide concentrations within this range suggesting that compliance was good in general

Discussion

Tocainide is a primary amine which in many respects is closely related to lidocaine

However in contrast to lidocaine tocainide is rapidly and completely absorbed from the gastrointestinal tract and the first pass effect is negligible In animal studies tocainide has been found to be effective by both the intravenous and oral route for suppressing experimentally induced cardiac arrhythmias[1,2] Several studies of the efficacy of the drug in ventricular arrhythmias of varying origin have been carried out in humans Winkle et al[3] found that serious chronic ventricular arrhythmias refractory to other antiarrhythmic agents could be controlled with tocainide in appropriate doses The study also showed that there was a correlation between the concentration of the drug in plasma and the antiarrhythmic effect Other investigators have reported similar results These studies have mainly comprised patients with arrhythmias due to coronary heart disease and previous AMI Experience with the use of tocainide for suppression of arrhythmias in the acute phase of myocardial infarction is still limited Since the drug has been shown to have attractive electrophysiologic and hemodynamic[6] qualities it should possibly be advantageous to use it in patients with AMI thereby combining the lidocaine like characteristics with oral availability In a study of the pharmacokinetic effects of tocainide on patients with AMI it was shown that it was possible to achieve the results of Winkle et al who suggested obtaining rapid therapeutic plasma concentrations by combining intravenous and oral administration This plasma level was maintained during steady state conditions and the regimen did not induce any important untoward effects It was therefore considered appropriate to perform a controlled investigation of the effects of tocainide in AMI

In the present study tocainide did not prevent VF symptomatic VT or sudden death in patients with AMI Because of the small number of patients enrolled in the study and the surprisingly low overall mortality rate it is not possible to conclude on statistical grounds that tocainide lacks the ability to prevent these events Some of the patients who developed serious ventricular arrhythmias had low plasma tocainide concentrations at the time of the event and in one patient VT which occurred despite an apparently adequate plasma tocainide concentration was controlled by increasing the dosage This suggests that it may be possible to improve arrhythmia control by increasing the dosage within the limits of patient tolerance This is obviously not possible in a double blind study The majority of patients achieved plasma tocainide concentrations in the range of 18 to 45 μmol/L as was expected from our initial pharmacokinetic study of patients with AMI[9]

The present study may indicate that the suggested therapeutic range is not generally valid but that higher concentrations are desirable in some patients Individual titration of the tocainide dose until the highest level tolerated has been found might be preferrable Further studies involving a greater number of patients and individually chosen dosages are thus necessary to determine whether or not tocainide can prevent VF symp

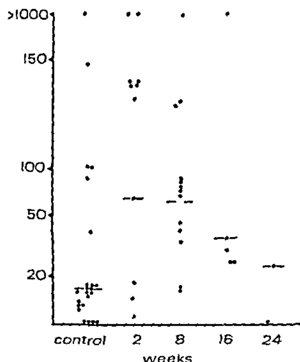

Fig 2 Number of ventricular ectopic beats found in 24 hours in placebo treated patients expressed on a log scale The bars indicate the median value

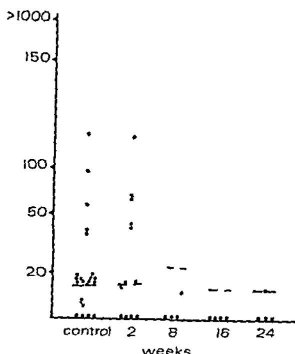

Fig 3 Number of ventricular ectopic beats found in 24 hours in tocainide treated patients expressed on a log scale The bars indicate the median value

of 97% The specificity however may appear to be exceptionally high if the number of false positive aberrant beats is related to the total number of beats in the 24 hour period With the adoption of this form of analysis specificity may be regarded as high as 99 9% The arrh th as detected by the computer were ind r r analyzed and confirmed visually by t observers

Plasma tocainide levels were estimated Astra Clinical Research Center Edinburgh effective p na level of tocainide would ap to be > 3 ml

Statistic lysis The basic design was of a group comp between two treatments Statistical test analysis were a χ test and Student s p A P value of < 0.05 was considered t ant

Results

Forty two tients had significant ventricular nd were withdrawn from the study patients had effective plasma le ompared with 27 patients receiv nide thus significantly reduced the incidence of serious ventricular arrhythmias ($P < 0.005$)

There was considerable individual variation in the number of ventricular ectopic beats in any 24 hours The range was 0 to 6 547 ectopic beats in 24 hours Consequently the results were expressed as the median number of ventricular ectopic beats per patient per day In the placebo patients the median value on admission was 14 ventricular ectopic beats per patient per day and increased to 67 a 68 at 2 and 4 weeks respectively This increase was maintained throughout the period of the study (Fig 2) In the tocainide patients there was no increase in the number of ventricular ectopic beats per patient The median number of ventricular ectopic beats per patient on admission was 11 and there was little or no increase—12 22 9 and 9 (Fig 3) Thus tocainide produced a significant reduction in the number of ventricular ectopic beats found with increasing mobilization in these postmyocardial infarction patients treated with placebo ($P < 0.01$) The hemodynamic effects of tocainide can be seen in Fig 4 There was little or no change in systemic blood pressure or in heart rate throughout the 6

placebo-treated patients. Frequent VPCs and/or VTs on any occasion during the first 24 hours occurred in 19% of tocainide treated patients and in 47% of those given placebo. This difference is statistically significant ($P < 0.05$). The percentage of patients with VT was significantly greater in the placebo group (41% compared to 13%, $P < 0.05$).

One and six months after inclusion in the study, fewer patients in the tocainide group had VTs, but because of the small number of observations this difference did not reach statistical significance (Table III). Notwithstanding this, the number of hours during which arrhythmias occurred was significantly less in the tocainide group at all assessment times except at 10 days.

Exercise induced ventricular arrhythmias. There were no significant differences between the maximum work loads achieved by the two groups at any observation period, nor between the heart rates and systolic blood pressures. In general, the reasons for discontinuation of exercise were similar in the two groups. The development of VTs, however, resulted in discontinuation of the exercise test in three patients given placebo on four occasions, while in the tocainide group no exercise tests were discontinued because of the development of such arrhythmias.

More patients in the placebo group developed VTs on exercise (Tables IV and V). Although the difference between the groups did not reach statistical significance at 1 and 3 months after AMI, the incidence of arrhythmic events in the placebo group was significantly greater at the 6-month exercise test ($P < 0.05$). A significantly greater number of patients in the placebo group had exercise arrhythmias on one or more occasions (13 compared to two, $P < 0.01$). Since VT did not occur after exercise in tocainide treated patients, the data suggest that tocainide was associated with a reduced incidence of serious ventricular arrhythmias in these patients. The greater number of patients with frequent paired and/or multifocal VPCs induced by exercise in the placebo group also supports this conclusion.

Tolerability. No clinically important changes in mean blood pressure or heart rate occurred within the 60 minute period following the injection of tocainide. There were no significant differences in mean blood pressure and heart rate between the tocainide and placebo treated groups 10 days, 1 month, 3 months, and 6 months after the start of treatment. Side effects following intravenous injection were more common in the tocainide-treated patients (n = 17) than in those receiving placebo (n = 3).

CNS symptoms were the most common side effects seen in the tocainide group and usually consisted of paresthesias described as a numbness in the throat, tingling sensations in the lips, a feeling of cold or warmth, and in a few cases a tingling sensation in the arms. CNS side effects were all reported as mild or moderate except in one patient who developed confusion 5 minutes after the start of tocainide injection (250 mg). The infusion was stopped and the patient was withdrawn from the study. The symptoms disappeared completely 10 to 15 minutes after the injection was terminated.

Gastrointestinal complaints were the next most common side effects in patients given tocainide. These usually included mild to moderate nausea followed by vomiting.

Cardiovascular side effects occurred in four patients in association with intravenous tocainide administration and consisted of a fall in blood pressure and heart rate. The injection was completed when the blood pressure stabilized following atropine and/or a short break in the infusion.

Withdrawals due to side effects. Nine patients

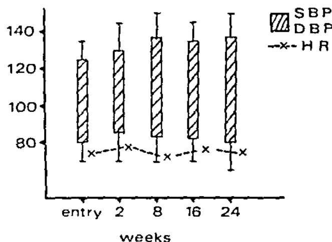

Fig 4 Effects of tocainide on systolic and diastolic blood pressure and heart rate The results are expressed as the mean and the standard error of the mean

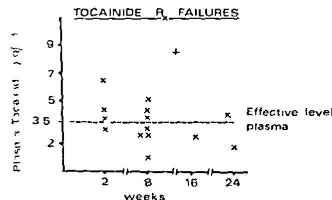

Fig 5 Plasma tocainide levels in patients who developed significant ventricular arrhythmias Dotted line indicates that the effective plasma level of tocainide is greater than 3 5 µg/ml + indicates sudden death in a patient

months Although this evidence is far from conclusive tocainide would not appear to produce a significant depressant effect on the myocardium

There was a high incidence of new cardiovascular events (15%) with four patients sustaining a further myocardial infarction and 18 patients developing angina pectoris of such severity as to justify the use of β adrenergic receptor blocking drugs

Fifteen patients were withdrawn from the trial because of unacceptable side effects that were considered by the attending physician to be related to their medication The detailed results are found in Tables II and III It can be seen that the incidence of lightheadedness in dyspepsia appeared to be higher in the tocainide treated patients A severe skin rash appeared in 3 of the 71 patients treated with tocainide There was a surprising similar incidence of central nervous system (CNS) symptoms in both treatment groups These complaints consisted of paresthesia and twitching with no objective clinical evidence of CNS pathology One patient developed allergic alveolitis while being treated with tocainide the drug was discontinued with some improvement but only after corticosteroid therapy was his lung function restored to near normal with improvement in symptoms

Neither significant ANA titers nor abnormal renal or hepatic function was found in any of the tocainide treated patients

Patient compliance as assessed by tocainide blood levels was excellent In three of the patients withdrawn from the study because of unacceptable side effects, with no objective evidence of pathology there was little or no tocainide found in the plasma

It is of interest that 7 of the 15 patients did not have effective plasma tocainide levels and significant ventricular arrhythmias were found in these patients It is perhaps of greater interest that significant ventricular arrhythmias could still occur despite high plasma levels of tocainide (Fig 5) Indeed sudden death occurred in a patient who had a plasma level of 9 1 µg/ml

Discussion

This study has demonstrated that tocainide is an effective antiarrhythmic agent in patients followed up for 6 months after an acute myocardial infarction The incidence of significant ventricular arrhythmias was reduced as was the increase in ventricular ectopic beats found in such patients known to have peptic ulceration or gastroesophageal reflux There was no conclusive evidence of a depressant effect on the myocardium

Adverse reactions contraindications lack of effectiveness and frequent drug administration with established oral antiarrhythmic therapy have stimulated the search for additional orally effective antiarrhythmic drugs In Europe amiodarone is used extensively and suppresses both supraventricular and ventricular arrhythmias It is particularly effective in the treatment of tachyarrhythmias associated with the Wolff Parkinson White syndrome The major side effect of

the transducer resolution still remains to be solved

More recently Silverman and associates[1] reported on the four chamber view in congenital heart diseases using an electronic sector scan In addition Ports and associates[11] measured the displacement of the STL in Ebstein s anomaly with this method It appears to be practical to utilize the apical cross section for the four chamber view according to their method when assessing the displacement of the STL from the right atrioventricular ring

However this approach also has its limitations In our experience we could not measure the displacement of the STL in the four chamber view in three out of the 11 patients in spite of the specific angiographic findings In one of the three the STL was not identified from the four chamber view whereas the rudimentary STL was found in the three chamber view by angulating the transducer in the direction B from the cardiac apex (patient M T) In another of the three patients (T T) the four chamber view disclosed no displacement of the STL although it was measured as 1 5 cm at cardiac operation

The downward displacement of the STL in our study was less than that reported by Ports and associates[11] This is probably attributable to the fact that there were milder forms of the anomaly in the majority of the patients examined Moreover attention should be paid to the differentiation of the STL from the trabeculae in the right ventricle The rudimentary STL should not be confused with other intracardiac structures To separate the STL from other echo origins it is important to carefully observe the movement of each component of subvalvular structures using the cinematography or video system Finally the downward displacement of the STL should be assessed in comparison with the findings at operation or autopsy in order to obtain the most appropriate cross section for the measurement

With regard to the subxiphoid approach Chang and Feigenbaum[1] reported they could overcome the limitations of the standard technics of M mode echocardiography It is well known that the patient with emphysema or a large barrel chest is very difficult to examine with the transducer along the left sternal border

Matsukubo and associates applied this method to the measurement of the right ventricular wall thickness Furthermore it has been extended to the field of cross sectional echocardiography using electronic sector scanning[13]

In Ebstein s anomaly the right sided heart chambers are extremely enlarged making it difficult to visualize the over all right ventricle from the apex to the base In this connection the subxiphoid approach seems useful to observe the right ventricular apex to the base as well as the tricuspid subvalvular apparatus However little has been reported on this and this is the reason we chose to undertake the present study

In order to clearly describe the tricuspid subvalvular structures we adjusted the gain setting and deepened the focal point in comparison with standard cross sectional technics The interpretable images were available with the subxiphoid approach except for the patients with liver enlargement or tight abdominal wall In contrast the displacement of the STL was detected by this technic only in three instances Thus the four chamber view is thought superior to the subxiphoid approach in the detection of the distorted STL whereas the subxiphoid cross section is recommended when other approaches are not suitable to obtain intracardiac information

Summary

Apex and subxiphoid cross sectional echocardiography was performed with an electronic sector scan on 11 patients having Ebstein s anomaly isolated or associated with other cardiac diseases For control study 10 normal subjects and 10 ASD patients were similarly examined

In the apical four chamber view the displacement of the STL was measured in end diastole using 8 mm cinematography It ranged from 1 4 to 3.2 cm with an average of 2 1 ± 0 5 cm in eight out of the 11 patients whereas in control subjects there was no displacement of the STL

From the apical three chamber view of the right side of the heart the downward displacement of the STL into the right ventricular cavity was also clearly visualized as well as the tricuspid valve ring Thus the right sided heart was seen to be divided into the functional and atrialized right ventricles and the right atrium by the displacement of the STL

In addition the CT inserting into the ATL was observed in five cases from the three chamber view and in four instances from the four chamber view

The interpretable subxiphoid cross sectional

images were obtained in nine of the 11 patients The right and left sides of the heart were widely visualized and the elongated ATL was fully observed from the tip to the thickened root Moreover the CT inserting into the ATL was visualized in six out of the nine patients

We are grateful to Mr Yoshihisa Kitamura for his technical assistance and to Mr John M Shields for correcting the English in this paper

this compound is the finding of corneal deposits in nearly all of the patients These deposits usually do not interfere with vision but may upset corneal metabolism [1]

Disopyramide is similar in its action to both quinidine and procainamide and like amiodarone is useful in the management of both supraventricular and ventricular arrhythmias Anticholinergic side effects including dry mouth blurred vision and urinary retention are not infrequent [1] Significant myocardial depression in patients with left ventricular dysfunction has recently been reported by Podrid et al

Mexiletine has similar electrophysiologic properties to lignocaine and thus is useful in the management of ventricular arrhythmias [1] Chamberlain has recently reported that mexiletine effectively suppressed ventricular arrhythmias in a group of postmyocardial infarction patients without however influencing the mortality rate A number of side effects have been reported consisting either of gastrointestinal problems such as nausea and vomiting or CNS problems with tremor ataxia and parasthesia

Tocainide would appear to be effective and to have relatively few side effects in a dosage of 400 mg t i d It is of interest that there were a considerable number of nonspecific side effects related to placebo therapy in this postmyocardial infarction group of patients CNS side effects might be anticipated with this analogue of lignocaine but in the dosage used in this study there was no objective evidence of CNS pathology despite complaints of lightheadedness tremor and paresthesia in some patients The similar incidence of CNS symptoms in the placebo group of patients emphasizes the need for caution in relating side effects to any form of drug therapy

It was noted that significant ventricular arrhythmias could occur despite adequate circulating levels of tocainide The particular assay used for the estimation of plasma levels was different from that used by other workers and the effective plasma level of tocainide in this study would appear to be a level greater than 3 5 μg/ml Winkle et al [8] have previously reported that tocainide was successful in controlling ventricular arrhythmias in 53% of patients proving unresponsive to quinidine procainamide or propranolol As in this study significant ventricular arrhythmias and sudden death could still occur despite more than adequate circulating blood levels of tocainide

Table III Side effects of therapy

Side effects	Malaise	Allergic lung disease	Insomnia	Polymyalgia
Tocainide	0	1	2	0
Placebo	2	0	?	1
Withdrawal				
Tocainide	0	1	1	0
Placebo	1	0	0	1

These results suggest that tocainide is a safe and effective antiarrhythmic agent in postmyocardial infarction patients but a larger number of patients is required before we can conclude that a reduction in ventricular arrhythmias is associated with a reduced mortality rate

Tocainide for drug resistant ventricular arrhythmias Efficacy, side effects, and lidocaine responsiveness for predicting tocainide success

Roger A Winkle M D Jay W Mason M D and
Donald C Harrison M D *Stanford Calif*

Tocainide therapy has been evaluated in 38 patients with ventricular arrhythmias Thirty-one had recurrent sustained ventricular tachycard a and/or fibr llation and 29 required prior cardioversions These arrhythm as could not be managed with quinidine procainamide disopyramide or propranolol Tocainide doses averaged 1 500 *mg/day (range 600 to 2 400) and the majority of pat ents had plasma* concentrations from 6 to 12 μg/ml Twenty two patients (61 /) had their arrhythmias controlled with tocainide and 16 (39 /) did not Tocainide dose and plasma concentrat ons were s milar for responders and nonresponders Lidocaine was effective in 26 patients and 16 (63 /) of these had their arrhythmias controlled with tocainide Of 12 patients in whom lidocaine was known to be ineffect ve or who had not been previously treated only two (17 /) had arrhythmias controlled with toca n de ($P < 0\ 02$) S de effects occurred in approximately two thirds of patients but required discontinuation of long term tocainide in only three patients

Tocainide is a lidocaine analogue that is effective for treating ventricular arrhythmias It has nearly complete bioavailability and a plasma half life averaging 13 5 hours Plasma concen tration is directly proportional to dose in individ ual patients and there is a narrow range of intersubject variation of plasma concentration for any dose Electrophysiologically tocainide resembles lidocaine and its primary hemody namic effect after intravenous dosing is a modest elevation of vascular resistance resulting in a slight rise in arterial pressure

This study reports our experience with the use of long term tocainide in a group of patients with severe ventricular arrhythmias that could not be managed with other generally available antiar rhythmic drugs We will examine the efficacy and side effects and the value of lidocaine responsive ness for predicting arrhythmia control with tocainide

Methods

Thirty eight patients with ventricular arrhyth mias are the subjects of this report This report includes and provides further follow up on the 17 patients reported on in 1978 Each patient had ventricular arrhythmias that could not be man aged adequately with currently available antiar rhythmic drugs All gave written informed con sent and the therapy was approved by the Stan ford Human Subjects Committee

For patients with frequent recurrent episodes of sustained ventricular tachycardia or ventricu lar fibrillation tocainide therapy was considered successful when control of these severe occur rences was established For patients with ventric ular ectopic activity tocainide was considered successful when there was nearly complete elimi nation of ventricular ectopic beats

Initial dosing with tocainide was undertaken for most patients at 400 mg every 8 hours The

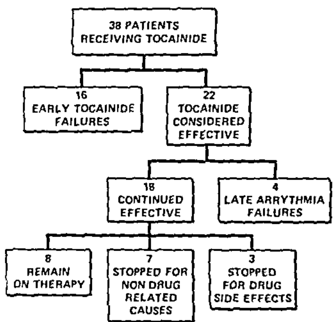

Fig 1 Outcome in 38 patients with ventricular arrhythmias treated with tocainide

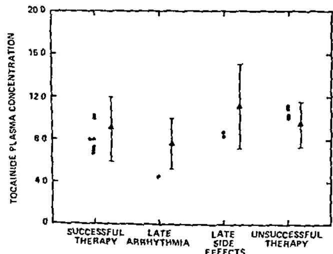

Fig 2 Mean tocainide plasma concentration over one dosing interval. Most patients plasma concentrations were between 6 and 12 μg/ml There was no significant difference between the plasma concentrations in those treated successfully and those treated unsuccessfully

dosage was gradually increased until arrhythmias were controlled or side effects occurred Frequent blood sampling was performed and plasma concentrations[13] given for each patient represent an estimate of the average over a dosing interval

For each patient assessment was made as to the responsiveness of the arrhythmias to lidocaine Comparison between the success or failure of tocainide in patients responsive or nonresponsive to lidocaine was performed by means of the Fisher exact test

Table 1 Response to lidocaine for predicting tocainide success

Tocainide	*Lidocaine effective*	*Lidocaine ineffective*	*Lidocaine not evaluated*
Effective	16	1	1
Ineffective	10	3	7
No effective/ total	16/26 (63%)	1/4 (25%)	1/8 (1[illegible]%)

Results

Patient population There were 38 patients (23 male 15 female) receiving tocainide the average age was 58 ± 12 years Twenty one had coronary disease seven had prior valve replacement, four had mitral valve prolapse three had a cardiomyopathy and three had an otherwise normal heart Congestive heart failure played a prominent role in the prior clinical course of 16 patients

The arrhythmia was sustained ventricular tachycardia and/or fibrillation requiring pharmacologic or electrical conversion in 31 patients Twenty eight patients had experienced more than one episode and 29 had a prior cardioversion In seven patients the arrhythmia was symptomatic ventricular ectopy

Thirty six patients had been treated unsuccessfully with quinidine (average daily dose of 1 5 ± 0 44 gm) 33 with procainamide (2 9 ± 1 1 gm) 28 with propranolol (140 ± 101 mg) and 11 with disopyramide (675 ± 324 mg)

Results of tocainide therapy The results of tocainide therapy are shown in Fig 1 Tocainide therapy was initially effective in 22 of the 38 patients (61%) Four had late arrhythmia recurrences including two who died of ventricular fibrillation after 3½ and 4 months of therapy Eighteen patients had their arrhythmias treated continuously and successfully with tocainide Three of these required discontinuation of the drug after 6 7 and 27 months because of side effects (see below) The remaining 15 patients were treated successfully with tocainide (median duration 13 months) Eight remain on tocainide and in seven it was discontinued for nondrug related causes (One had a spontaneous decline in arrhythmias two died after coronary bypass sur

Open clinical studies at a referral center Chronic maintenance tocainide therapy in patients with recurrent sustained ventricular tachycardia refractory to conventional antiarrhythmic agents

James D Maloney M D Roger G Nissen M D and J M McColgan B S *Rochester Minn*

Chronic maintenance tocainide therapy was effective in controlling symptomatic recurrent ventricular tachycardia in 11 of 15 patients Patients were selected for tocainide therapy on the basis of refractoriness to conventional antiarrhythmic agents and responsiveness to the intravenous administration of lidocaine Side effects were frequent but could usually be managed by taking the drug with meals or by more frequent administration of smaller doses Survival frequency of symptomatic tachycardia frequency of asymptomatic ventricular tachycardia and tolerance of the therapeutically effective dosage were the criteria used to assess therapeutic effectiveness Factors common to the response group included primary and secondary Q T prolongation before therapy a paradoxical increase in ventricular ectopic activity with quinidine like medications and shortening of the Q T interval with maintenance tocainide therapy These factors may prove to be useful in identifying the patients who are most likely to benefit from chronic maintenance tocainide therapy

During the last 400 years the science of medicine has evolved through the use of descriptive analysis experimental investigation modern mathematics and technologic advances The value of descriptive analysis is exemplified by Withering s report in 1785[1] on the use of foxglove *(Digitalis purpurea)* In the report his observations of 10 years on drug preparation dose effect and adverse reactions were analyzed Withering cautioned his readers that no general deductions decisive upon the failure or success of the medicine can be drawn from the cases I now present I wish the reader to keep in view that it is not my intention merely to introduce a new diuretic to his acquaintance but one which though not infallible I believe to be [of] use After all in spite of opinion prejudice or error TIME will fix the real value upon this discovery

The importance of these clinical observations persists today The reasons for initiating therapeutic trials are to confirm the useful properties of a drug device or procedure to define the adverse side effects and to provide a potentially effective intervention for patients with disabling conditions that are refractory to all available therapy[2] In keeping with these goals our experience with tocainide a lidocaine analogue obtained through an emergency open clinical study for patients with refractory ventricular tachycardia is presented

Selection of patients

From June 1977 to April 1980 seventy eight patients hospitalized at our institution with symptomatic recurrent ventricular tachycardia

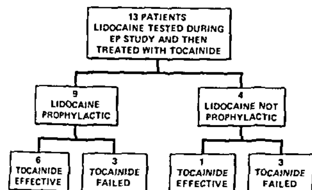

Fig 3 Outcome in 13 patients in whom lidocaine was tested for protection against ventricular tachycardia induced during intracardiac electrophysiologic study Although the acute response to lidocaine was fairly predictive of the long term success or failure of tocainide the correlation was imperfect

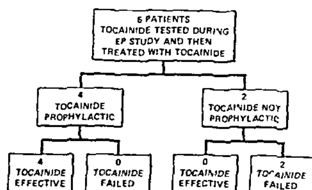

Fig 4 Outcome in six patients undergoing a repeat electrophysiologic study to evaluate ventricular tachycardia inducibility on oral tocainide Although the number of patient is small there was a perfect correlation between the outcome of the electrophysiology study and long term therapy

gery was performed for angina one died of lung carcinoma and three died of heart failure)

Sixteen patients failed to have their arrhythmia controlled with tocainide despite maximally tolerated doses of tocainide The median duration of treatment in these patients was 7 days

Dose and plasma concentration The total daily dose of tocainide ranged from 600 to 2 400 mg daily There was no difference between the daily dose of those treated effectively (1 528 ± 379 mg/day) as compared to those treated ineffectively (1 514 ± 412 mg/day) There was no difference between the plasma concentration for those responding to tocainide (8.9 ± 3.1 gm/ml) and those not responding (9.4 ± 2.2 μg/ml) (Fig 2)

Lidocaine responsiveness for predicting tocainide success Since many of these patients were referred because their arrhythmia was responsive to lidocaine we evaluated the value of a good lidocaine response for predicting the success of tocainide Table I summarizes the results Tocainide therapy was successful in 63% of patients in whom lidocaine was considered effective Tocainide was successful in only two (17%) of the other 12 patients in whom lidocaine was ineffective or in whom it was not evaluated The difference between these groups is statistically significant ($P < 0.02$)

There were 13 patients in whom lidocaine was tested during an electrophysiologic study (Fig 3) Lidocaine protected against induced ventricular tachycardia in 9 of these 13 Six of these nine had successful oral tocainide therapy Lidocaine did not protect against ventricular tachycardia in four patients In three of these patients tocainide therapy was a failure Of six patients in whom oral tocainide was tested during a second electrophysiologic study (Fig 4) four were treated successfully Both patients for whom tocainide was not prophylactic at the time of electrophysiologic study had subsequent spontaneous recurrences of ventricular arrhythmias Lidocaine responsiveness during the electrophysiologic study may aid in selecting patients for oral tocainide therapy However all patients should be retested with tocainide prior to hospital discharge

Side effects Two thirds of patients had side effects (Table II) Side effects occurring during chronic oral therapy tended to be infrequent and were usually not a serious limitation to tocainide therapy Tremor was minimized by taking the drug with food

Three patients had severe side effects during long term therapy and required discontinuation of tocainide One had a prior history of idiopathic and procainamide induced pericarditis Tocainide was stopped after 7 months because of anemia fever and pericarditis Another developed severe arthralgias and arthritis involving the hands after 4 months of therapy which resolved when tocainide was discontinued There was a slight rise in the antinuclear antibody titer This patient had undergone a brief treatment with procainamide 2 months earlier The third patient had an immunologic side effect that seemed best attributed to tocainide After 27 months the patient presented with gross hematuria and had a rise in creatinine

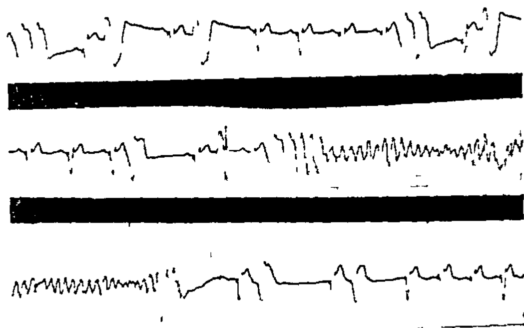

Fig 1 Case 1 Continuous monitoring strip recording of ventricular flutter occurring after second open heart surgery and use of quinidine sulfate

refractory or intolerant to conventional therapy (quinidine procainamide disopyramide propranolol and digitalis—alone or in combination) entered open clinical trials of investigational drugs devices or procedures Seventeen of these patients were managed with cardiac surgical procedures guided by epicardial and intramural electrophysiologic mapping techniques[5] Nine patients received investigational pacing devices for burst ventricular overdrive conversion[6] or dual chamber atrioventricular sequential pacing for control and prevention of ventricular tachycardia associated with intermittent symptomatic bradycardia Fifty seven patients participated in open clinical drug trials of mexiletine verapamil aprindine or tocainide[9] Assignment of an individual patient to a specific drug trial was determined on the basis of the underlying myocardial disease the electrophysiologic characteristics of the tachycardia and the clinical judgment of the attending physician Five patients participated in more than one of the clinical trials Fifteen patients entered the tocainide drug trial and provide the data for this report

Material and methods

Definitions An open clinical study (trial)[1] is defined as a clinical experiment with an investigational drug device or procedure which is applied to achieve a specific outcome and which is known to the patient and to the physician A control or comparison group attained through randomization techniques and the administration of placebo agents are excluded

Ventricular tachycardia is paroxysmal wide complex tachycardia that fulfills the standard electrocardiographic or electrophysiologic (or both) criteria[11]

Chronic recurrent ventricular tachycardia is symtomatic ventricular tachycardia that is documented two or more times and occurs in the absence of an acutely evolving process such as recent myocardial infarction

Sustained paroxysmal ventricular tachycardia is tachycardia lasting for more than 30 seconds or requiring emergency treatment because of hemodynamic collapse or progression to ventricular fibrillation

Torsade de pointes[1] is a variant of rapid ventricular tachycardia which has a surface ECG pattern characterized as a screwlike pattern (rhythmically changing polarity of the QRS deflection as if the sequence of depolarization were turning about the point)

Q T prolongation[13,14] is defined as Q T and Q T intervals obtained from the standard elec

Table II Tocainide side effects

Side effects	*Dose finding (N = 38)*	*Chronic therapy (N = 24)*

to 2 7 mg/dl A renal biopsy showed an immune complex glomerulonephritis This was a nonmembranous glomerulonephritis with immune complex deposition in both the mesangium and the basement membranes Immunofluorescent staining was positive for IgG IgM IgA and C 3 was deposited in a granular pattern (Fig 5) There was no rise in antinuclear antibody titers and antibodies to native DNA were negative With drawal from tocainide resulted in a gradual improvement in renal status

Discussion

This report summarizes our experience with tocainide in a group of patients with severe and life threatening ventricular arrhythmias difficult to manage with standard antiarrhythmic drugs Conclusions from such studies must be made with caution It is difficult to standardize therapy and to make carefully controlled observations with regard to efficacy and side effects Nonetheless our data suggest that tocainide is a valuable antiarrhythmic drug for the management of such patients

This study suggests a reasonable correlation between responsiveness to lidocaine and successful outcome of tocainide therapy An important unanswered question is the tocainide response rate of patients not preselected because of lidocaine responsiveness Only one of eight patients in whom the lidocaine responsiveness status was unknown responded to tocainide In our study the apparent success of tocainide may in large part be due to the fact that patients were preselected because of their lidocaine responsiveness Nonetheless the availability of oral tocainide for patients responsive to lidocaine does represent a valuable addition to our list of antiarrhythmic drugs

Our data suggest that testing intravenous lidocaine in the electrophysiology laboratory[1] can be of value for selecting patients who have a high likelihood of arrhythmia control with tocainide All patients who respond to lidocaine in the electrophysiology laboratory should undergo subsequent electrophysiologic testing on oral tocainide

The range of plasma concentrations associated with excellent arrhythmia control for tocainide was generally from 6 to 12 μg/ml The plasma concentrations associated with side effects were probably only marginally higher than the therapeutic range since many patients were treated with doses just below those associated with side effects For most patients the dose was 400 500 or 600 mg every 8 hours The doses and plasma concentrations for those patients failing tocainide were in the same range as those in patients who had a good response In this study drug plasma concentrations were measured only in retrospect and did not play any role in the management of the patients For these critically ill patients we preferred to increase the tocainide dose to the point where side effects developed and then diminish it slightly Such a practice is reasonable with tocainide since the side effects occurring when patients are under careful observation are minor and resolve promptly and there seems to be little danger of creating serious conduction disturbances or potentially lethal arrhythmias

Although side effects occurred in two thirds of the patients they required drug discontinuation in less than 10% of patients The commonest side effect was a slight tremor most often noted in the upper extremities Nausea was the second most common side effect The three patients requiring discontinuation during long term therapy all experienced immunologic side effects In two of the three it was not certain that tocainide was the

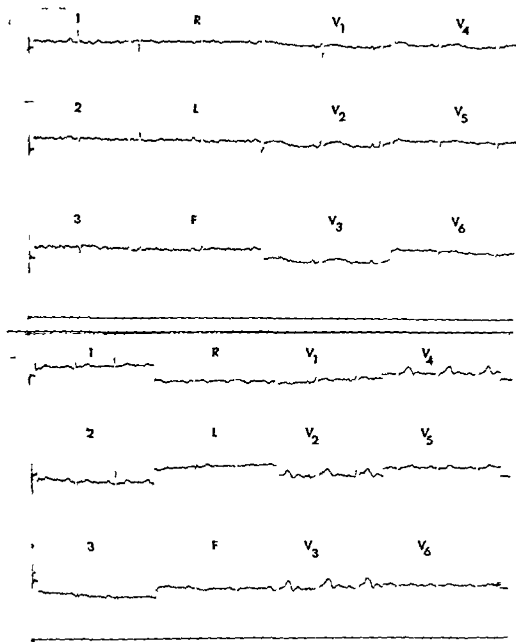

Fig 2 Case 10 *Top* Electrocardiogram recorded 8 days after cardiac arrest (April 8 1978) Pronounced repolarization abnormalities and prolonged Q T intervals are present *Bottom* Electrocardiogram recorded while patient was receiving 2 400 mg tocainide/day (May 9 1978) Repolarization abnormalities and prolonged Q T intervals have improved

trocardiograms and vectorcardiograms which are 10 msec or more beyond the upper limits of normal for age sex and cycle length

Quinidine like medications include quinidine procainamide and disopyramide—antiarrhythmic agents that have membrane stabilizing properties combined with prolongation of the action potential duration

Protocol design and entry criteria All patients entering the emergency open clinical study were hospitalized at our institution for the diagnosis and treatment of recurrent symptomatic ventricular tachycardia or ventricular fibrillation and associated heart disease All but two of the patients were referred from other medical facilities because of therapeutic unresponsiveness The

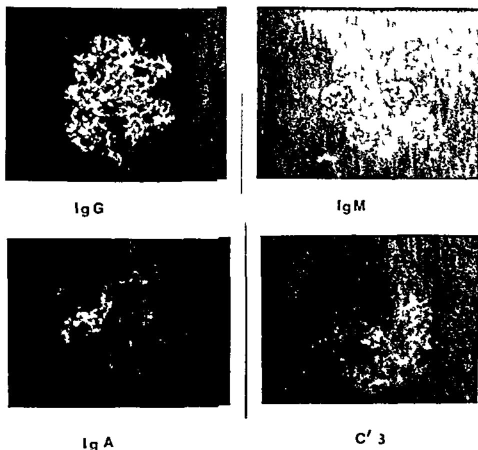

Fig 5 Immunofluorescent stains from renal biopsy of the patient who developed glomerulonephritis There is an irregular lumpy bumpy pattern of immune complex deposition in the glomerulus

precipitating factor One patient had immune complex glomerulonephritis without a rise in the antinuclear antibody titer suggesting that the antibodies formed may not cross react with nuclear proteins

One potential advantage of tocainide may be its minimal arrhythmogenic potential Although one patient in our series may have had ventricular irritability increased by tocainide the drug seemed remarkably free of aggravation of serious arrhythmias Tocainide slightly diminishes the right ventricular effective refractory period and has no significant effect on Q T interval It would not be expected to cause the usual type of drug induced *torsade de pointe* Although many of our patients had severe heart failure the drug was well tolerated However the hemodynamic effects of tocainide after oral therapy have not been well studied and the drug should be used with caution in patients with uncontrolled heart failure We did not observe worsening of conduction disturbances but caution should be exercised in patients with severe conduction abnormalities

In summary tocainide is a useful addition to the group of drugs available to treat severe refractory ventricular arrhythmias We had a reasonable success rate in a group of patients predominantly selected for tocainide because of known responsiveness to lidocaine Further studies will be required to evaluate the drug s effect in less critically ill patients in patients not necessarily responsive to lidocaine and in those who have been treated successfully with other antiarrhythmic drugs The drug requires careful individual patient titration to achieve optimal antiarrhythmic effect and to minimize the occurrence of side effects Most side effects are mild and respond to minor dose adjustments Occasionally the drug must be discontinued because of immunologic side effects during long term therapy

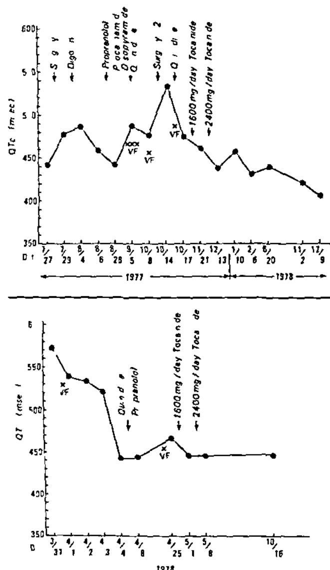

Fig 3 Time course change in corrected Q T intervals. Q T intervals were computed from Bazett s formula Q T = Q T ÷ $\sqrt{RR}$ *Top* Case 1 Q T intervals remained near normal during 1979 and 1980 and the patient has been free of recurrent ventricular tachycardia–ventricular fibrillation *Bottom* Case 10 Q T intervals have remained in normal range throughout 1979 and 1980 and the patient has been free of ventricular tachycardia–ventricular fibrillation

diagnosis of symptomatic refractory recurrent sustained ventricular tachycardia was accepted when (1) ECG or intracardiac electrophysiologic (or both) recordings confirmed the arrhythmia diagnosis and (2) near maximal amounts of commonly available antiarrhythmic agents alone or in combination were unsuccessful in preventing spontaneously occurring sustained ventricular tachycardia or ventricular fibrillation Plasma drug levels were used for determining unresponsiveness and patient compliance If the clinical history referral hospital records or plasma drug levels corroborated unresponsiveness or intoler ance the same therapeutic trial was not routinely repeated When the arrhythmia diagnosis was uncertain and the response to a specific antiar rhythmic therapy difficult to assess His bundle recordings combined with programmed ventricu lar stimulation or other provocative testing tech niques were used to evaluate the patient s statu Serial ventricular stimulation studies were use to assess the therapeutic effectiveness in thos patients with reliably induced and terminate ventricular tachycardia [13]

Refractoriness to conventional antiarrhythmi agents combined with responsiveness to intrave nously administered lidocaine was required (each patient before entry into the clinical tria All participants were informed of the experimen tal nature of tocainide and gave written conser prior to entry The therapeutic goals for eac patient were predefined and included (1) surviva (2) prevention of recurrent sustained ventricula tachycardia and associated hemodynamic co lapse (3) prevention of spontaneously occurrin sustained and nonsustained ventricular tachyca dia and (4) attainment of a satisfactory balanc between control of ventricular tachycardia an unacceptable adverse reactions to tocainide

Results

Characteristics of patients All 15 patients ha well documented recurrent ventricular tachyca dia before entering the open clinical trial Th duration of symptoms before referral ranged fro 2 months to 6 years The ages of the 15 patien (10 males and 5 females) ranged from 9 to years Oral tocainide therapy was maintaine from 4 days to 34 months All patients who we responsive and tolerant to tocainide were chronic maintenance therapy for more than months Eleven of the 15 patients continued chronic maintenance therapy Five patients ha been withdrawn from the study (unresponsiv one patient intolerant three patients responsi and tolerant but withdrawn at aortic valve pro thesis replacement one patient) Three of the five patients have died two with document ventricular tachycardia–ventricular fibrillatio None of the patients has died while on tocaini therapy

The most frequent cause of the underlyi heart disease in this patient group was corona heart disease with previous myocardial infarctio

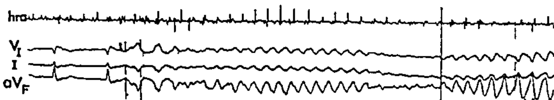

Fig 4 Case 1 Ventricular flutter with shifting axis *(torsade de pointes)* induced by paired ventricular extrastimuli at S S intervals of 220 to 250 ms while patient was receiving 1 600 mg tocainide/day Note atrial fibrillation previously induced by rapid atrial pacing hra = high right atrial electrogram Other intracardiac recordings have been omitted V I and aV are standard ECG leads

Four of the six patients with this condition have withdrawn from the study Five patients had primary myocardial disease presenting as congestive cardiomyopathy Two patients had generalized ventricular dilatation and hypokinesis one after surgical replacement of an aortic valve prosthesis and the other after revision of a ventricular-pulmonary artery conduit and residual ventricular septal defect[1] One patient had normal ventricular function and chronic active myocarditis diagnosed on the basis of findings on serial right ventricular biopsy specimens and cardiac catheterization One patient had recurrent ventricular tachycardia in the absence of clinically detectable heart disease

Invasive hemodynamic and angiographic data of recent cardiac catheterizations were available for 13 of the 15 patients Thirteen patients were in New York Heart Association Functional Class III or IV for dyspnea Ten patients had cardiomegaly and 11 patients required chronic maintenance digitalis therapy for congestive heart failure Twelve of the patients had been successfully resuscitated and defibrillated on two or more occasions Six patients had had previous open heart surgical procedures

Seven patients had histories of quinidine induced syncope[7] or a paradoxical increase in ventricular ectopic activity while taking quinidine and quinidine like drugs (Fig 1) In one of these seven patients the administration of quinidine procainamide and disopyramide consecutively produced spontaneously occurring ventricular tachycardia and ventricular fibrillation Although ventricular ectopy was frequent in all seven patients ventricular fibrillation had not occurred in the absence of these drugs Electrocardiograms demonstrated Q T prolongation in 11 patients The Q T prolongation was unrelated to identifiable factors in five patients and was secondary to quinidine like drugs in six patients Diffuse repolarization abnormalities presenting as prominent U waves were common The prolonged Q T intervals decreased during tocainide therapy (Fig 2) Ventricular fibrillation was most likely to develop when the Q T intervals were prolonged because of myocardial injury or drugs (Fig 3)

His bundle electrocardiography combined with programmed ventricular stimulation studies was performed in 10 patients Sustained ventricular tachycardia could be induced and terminated in seven however in four patients the tachycardia was rapid hemodynamically unstable and had a shifting electrical axis on the surface electrocardiogram consistent with the atypical ventricular tachycardia *torsade de pointes* (Fig 4) and required emergency cardioversion A similar type of ventricular tachycardia-ventricular fibrillation occurred in a 9 year old child receiving tocainide alone The episode of atypical ventricular tachycardia was precipitated by burst exercise and terminated spontaneously several seconds after the child collapsed The addition of propranolol (20 mg four times a day) to tocainide decreased exercise induced ectopy and prevented further ventricular fibrillation

Maintenance tocainide therapy ranged from 600 to 3 200 mg daily (1 200 to 3,200 mg daily for adults) The daily maintenance dose was determined by increasing the dosage every 2 to 3 days until the predefined therapeutic goals were achieved or until adverse side effects necessitated a decrease in dosage Steady state plasma concentrations were not immediately available On retrospective review effective plasma concentrations ranged from 5 to 19 μg/ml Blood levels higher than 13 μg and daily tocainide doses higher than 2 400 mg were usually intolerable

Drug tolerance and side effects No patient was completely free of side effects during the

.fety evaluatıon of tocaınide ın the American ıergency Use Program

ıs a report of the safety evaluation of tocaınide in the first 369 patients entered into the American nide Emergency Use Program This humanitarian protocol has made tocainide available for ıergency use in the treatment of l fe threatening intractable ventricular arrhythm as in patients who vere *unresponsive to or unable to take the approved antiarrhythmic drugs The most frequent adverse* xperiences reported were neurolog c and gastro ntestinal in nature and included dizz ness ghtheadedness tremors nausea vomiting and anorexia Adverse experiences resulted in the scontinuation of tocainide in 16 / of these patients and were transient and revers ble with no onclusive evidence of permanent organ injury Adverse experiences having special relevance to the ıfety assessment of new antiarrhythmic agents are discussed includ ng congestive heart failure rrhythm as and conduction disturbances convulsions lupus erythematosus like illness and deaths wh le n therapy No significant abnormal trends were observed in routine hematolog c and biochemical ıboratory screen ng tests or in ophthalmolog c or chest x-ray exam nations An evaluation of the effects l chronic tocainide adm nistration on ECG intervals showed no s gnificant change in P R or QRS ıtervals but demonstrated a statistically sign f cant decrease in Q T duration It is concluded that n atients with life-threatening ventricular arrhythmias tocainide is a safe agent with a favorable risk enefit ratio

?ocaınide a new lidocaine like oral antiarrhyth nic agent has been studied extensively in ılanned protocols [1-4] In addition this membrane ıctive agent has been available since 1974 for ·mergency use in patients with intractable ven ricular arrhythmias Consequently the Ameri :an Tocainide Emergency Use Program has pro ıided a unique opportunity to evaluate the safety ıf tocainide in seriously ill patients treated with he drug for periods up to 41 5 months The first 369 patients admitted to the program between November 30 1974 and September 30 1978 are he subject of this report These patients entered :he protocol in response to requests by their physicians who had reached an impasse in the management of their life threatening refractory ventricular arrhythmias Over 200 practicing physicians participated in the program as investiga tors during this 4 year period

The criteria for entering the program were that the ventricular arrhythmias were considered to be life threatening and the patients were unrespon sive to or were unable to take (intolerance or contraindication) the approved antiarrhythmic drugs quinidine procainamide propranolol and subsequently disopyramide

Upon entry into the protocol, 60% of these patients were in New York Heart Association Class III or IV demonstrating respectively mod erate or severe compromise of cardiac status Seventy one (19%) patients were treated with tocainide for over 1 year 51 (14%) for 6 to 12 months, and 107 (29%) for 1 to 6 months

Clinical parameters in safety assessment

Most frequent adverse experiences reported In a long term open label open-ended study of patients with severe underlying heart disease

†One patient withdrew from trial at 21 months for surgery died of left ventricular failure after valve replacement

‡Three patients (all in the group that withdrew) died two died of ventricular tachycardia ventricular fibrillation

entire treatment period in part because of the dosing technique and the patient population Although pharmacokinetic studies suggest that dosing intervals every 8 to 12 hours should result in maintenance of adequate blood levels for suppression of ventricular ectopy we found that 6 hour dose intervals were more effective in suppressing malignant arrhythmias while minimizing dose related side effects Four patients required drug administration five to six times per day in order to achieve tolerance Mild side effects of the central nervous system were experienced by all patients Ten of the patients complained of mild to severe nausea Vomiting was infrequent Gastrointestinal intolerance and a diffuse skin rash developed in three patients during the first week of therapy and these side effects necessitated the subsequent withdrawal of the three patients from the drug trial on days 7 8 and 31 respectively One additional patient developed a mild rash that was managed by temporary dose reduction In addition to dizziness tremulousness and paresthesias a common side effect of the central nervous system consisted of memory loss and a decreased ability to work with numbers Although there was a wide variation among individual patients the presence and severity of most side effects were closely related to the size of each individual dose and the total daily dose In general side effects decreased with time and could be reduced by either taking the drug with meals or taking it more frequently

Drug efficacy Thirteen of the patients had a favorable response with tocainide alone or in combination In one patient the combination of tocainide and propranolol was effective whereas tocainide alone was associated with increased ventricular ectopy The one patient who was withdrawn from the study at 4 days because of unresponsiveness had paroxysmal ventricular tachycardia associated with acute coronary insufficiency The arrhythmia was no longer refractory to lidocaine analogues after saphenous vein bypass surgery None of the patients died while receiving maintenance tocainide therapy whereas three of the five patients withdrawn from the drug trial because of intolerance died

Drug efficacy as determined by the predefined therapeutic goals is summarized in Table I Two patients had syncope secondary to paroxysmal sustained ventricular tachycardia–ventricular fibrillation Both patients had omitted one or two medication doses just before the episode Both patients required hospitalization and were successfully managed Prolonged ECG monitoring obtained during rehospitalization and through periodic ambulatory ECG monitoring demonstrated a decrease in sustained and nonsustained ventricular tachycardia Partial or total tocainide withdrawal during follow up hospitalizations resulted in an increase in ventricular ectopic activity in seven patients Eight patients have had improvement in their exercise tolerance and have less exertional dyspnea A clinically significant negative inotropic effect of tocainide has not been observed Seven patients have had reassessment of left ventricular function by echocardiography radioisotope imaging or catheterization techniques during the follow up period Comparisons of cardiac index wall motion chamber size and left ventricular end diastolic pressure also suggest that tocainide is well tolerated hemodynamically even when used for patients with poor left ventricular function

Discussion

Life threatening ventricular arrhythmias remain a therapeutic challenge The currently available antiarrhythmic agents are often ineffective or are not tolerated because of adverse side effects Occasionally these agents will increase ventricular ectopy and the vulnerability to ventricular fibrillation When patients with symptomatic or asymptomatic ventricular tachyarrhythmias are being treated the implied thera

associated with life threatening refractory ventricular arrhythmias one should anticipate the reporting of a number of adverse experiences because of the long duration of exposure to a variety of factors This was the case in the Emergency Use Program as most patients reported one or more adverse experiences at some point during the entire period of treatment Table I shows the percentage occurrence of the most frequent adverse experiences in the 369 patients in this study The sources of data for this table include not only documented information from the conventional investigator s data form but also all other available information some of which may be considered undocumented The latter sources include hospital and office charts physician s and nurse s notes physician s correspondence and reports of the sponsor s site visits and telephone contacts Patients were included in this table if an adverse experience occurred only once during the entire period of treatment The majority of reported adverse experiences were neurologic or gastrointestinal in nature The neurologic experiences appeared to be related to dosing indicating a possible relation to peak blood levels and penetration of the blood brain barrier such as occurs with lidocaine Although these mostly subjective experiences were sometimes distressful for the patients they were usually transient in nature and reversible with no evidence of permanent organ injury

Adverse experiences resulting in discontinuation of tocainide The adverse experiences of greatest importance were those severe enough to result in the discontinuation of tocainide therapy This occurred in 60 (16%) of the patients in the program The frequency distribution of these adverse experiences is provided in Table II Only rarely was a causal relationship between tocainide and the adverse experience tested by a rechallenge with tocainide In dealing with severely ill patients it is difficult to establish cause and effect relationships for any drug and particularly difficult for an antiarrhythmic agent Neurologic and gastrointestinal adverse experiences were a primary cause of discontinuation in 48 of the 60 dropouts (80%)

Rash was the only adverse experience accounted for four patient discontinuations In two patients recurrence of the rash was observed following rechallenge with tocainide While fever was reported as an adverse experience in only one subject did it subside with discontinuation of tocainide and return with rechallenge One patient was discontinued because of hepatitis confirmed by a liver biopsy that could not distinguish between infection and a drug reaction Cytomegalovirus was suggested as a possible etiologic agent by the investigator Another patient was discontinued because of elevated liver enzymes This patient had aortic valve replacement just prior to starting tocainide and the possibility of a serum hepatitis must be considered One patient was discontinued (after receiving 1 400 mg of tocainide over 24 hours) because of the development of acute pulmonary edema 5 hours after the last dose The patient had a previous left ventricular aneurysmectomy and was in New York Heart Association Functional Class IV Understandably this patient was not rechallenged and other possible inciting factors could not be completely ruled out One patient was discontinued because of the development of polyarthritis and an elevated antinuclear antibody (ANA) titer The investigator stated that other explanations could not be dismissed such as the concurrent treatment with disopyramide and the recently discontinued procainamide One patient was discontinued because of recurrent pericarditis associated with an elevated ANA titer both of which antedated the onset of tocainide therapy One patient developed what appeared on chest x ray films to be an interstitial

peutic goal is to prevent spontaneous sustained ventricular tachycardia-ventricular fibrillation and sudden cardiac death Preventive treatment is based on the assumptions that (1) a reduction in ventricular ectopic activity decreases vulnerability to ventricular tachycardia-ventricular fibrillation and (2) the reduction in ventricular ectopic activity reflects the clinically significant antiarrhythmic properties of the drug in question

Recent studies have challenged these assumptions Frequency of premature ventricular contractions and various grades of ventricular ectopy short of bursts of ventricular tachycardia may have limited predictive value in identifying high risk patients[19] Also the large day to day variability in ventricular ectopy makes attributing the change in frequency of premature ventricular contractions to a specific antiarrhythmic agent hazardous The value of programmed ventricular stimulation techniques in identifying high risk subset patients and defining effective long term antiarrhythmic programs remains uncertain In this setting clinical observations and descriptive analysis over a long period are essential for documentation of clinically significant antiarrhythmic benefits The end points of (1) survival (2) paroxysmal tachycardia with hemodynamic collapse and (3) symptomatic nonsustained ventricular tachycardia can be clearly defined so that conclusions regarding drug efficacy for an individual patient are possible In this highly selected patient group tocainide was therapeutically useful Conclusions regarding antiarrhythmic drug efficacy in a nonselected population should not be drawn from our experience However awareness of several factors common to this group may be useful in identifying patients likely to benefit from tocainide therapy These factors include responsiveness to intravenously administered lidocaine quinidine induced syncope or increasing ventricular ectopy with quinidine like medications primary or secondary Q T prolongation and shortening of the Q T interval with maintenance tocainide therapy

Supporting the importance of prolongation of the Q T interval Haynes et al[3] reported a high incidence of Q T prolongation and repolarization abnormalities in patients surviving out of hospital ventricular fibrillation and also noted the continued high risk for repeat episodes of ventricular fibrillation The association between sudden death and Q T prolongation also has been described for postinfarction patients[7] and for patients with hereditary prolongation of the Q T interval The frequent occurrence of Q T prolongation quinidine induced syncope and *torsade de pointes* may reflect specific electrophysiologic mechanisms that are advantageously modified by tocainide or lidocaine These patients may represent a specific subgroup of patients who are likely to benefit from tocainide therapy Additional investigation is needed to substantiate these relationships

Simultaneous maintenance digitalis and tocainide therapy was used in 11 of our patients without untoward clinical effects or without alterations in expected blood levels Combination antiarrhythmic therapy consisting of propranolol and tocainide or quinidine like drugs and tocainide improved antiarrhythmic control achieved by a single drug in higher concentrations Combination therapy permitted lower dosages and reduced side effects This apparent complementary interaction probably reflects the different electrophysiologic actions of the drugs and emphasizes the potential importance of an oral lidocaine analogue Irreversible side effects were not observed in this series Side effects were common and generally were related to the size of each dose and the total number of milligrams per day Careful titration between drug efficacy and intolerable side effects can be achieved in most patients

This experience suggests that tocainide has a place in the treatment of refractory ventricular tachycardia and that chronic maintenance tocainide therapy may be particularly beneficial for patients who are responsive to intravenously administered lidocaine who present with prolonged Q T intervals and who are unresponsive to quinidine like agents

pulmonary edema that persisted despite diuretic therapy A lung biopsy was interpreted as showing interstitial pneumonitis This patient was afebrile with no rash or joint symptoms and had a normal white cell count and ANA titer Tocainide was stopped and treatment with corticosteroids begun after which pulmonary function and chest x ray findings improved She was not rechallenged with tocainide and other possible causes were not ruled out

Special adverse experiences in antiarrhythmic therapy In the safety evaluation of a new antiarrhythmic agent there are several adverse experiences of particular importance These include increased congestive heart failure increased ventricular arrhythmia aggravation of preexisting cardiac conduction disturbances convulsions and a lupus erythematosus–like syndrome In the Emergency Program no causal relationship with tocainide to these experiences could be definitely established Even if a causal relationship were established between tocainide and such effects the comparison with conventional antiarrhythmic agents would be most favorable

Table III exhibits these special adverse effects for the 369 Tocainide Emergency Program patients There were five patients in whom the initiation of tocainide therapy was reported to have possibly aggravated severe preexisting heart failure All five patients were in New York Heart Association Functional Class IV before tocainide treatment Three had a diagnosis of cardiomyopathy and two had coronary disease with old myocardial infarction Only one of the patients was discontinued because of this experience and four of the patients were known to subsequently die of heart failure It is of interest that a number of patients who were unable to tolerate disopyramide or propranolol because of heart failure were subsequently able to tolerate tocainide

Only four patients who received an adequate trial of tocainide therapy were stopped because of an alleged increase in ventricular arrhythmia occurring during initiation of therapy Of interest at least eight long term tocainide responders with abolition or substantial reduction of life threatening arrhythmic events while on tocainide had been uncontrolled and had manifested a prolonged Q T interval during prior treatment with quinidine procainamide and disopyramide

There were two patients with preexisting cardiac conduction disturbances that may possibly have been aggravated by tocainide although other explanations exist for the observed conduction changes One patient who exhibited transient second degree A V block was concurrently receiving digoxin and a beta blocker and was continued on tocainide for 36 months without any subsequent conduction problem The other patient had advanced degrees of A V block but had recently undergone mitral valve replacement which may be associated with transient or permanent changes in A V conduction

Convulsions were reported to occur in two patients while on tocainide no other obvious explanation for these convulsions exists Both patients were women over 80 years of age one

Table II Adverse experiences resulting in discontinuation among 369 patients

Adverse experience	*No of patient*

had previous brain damage from multiple cardio pulmonary resuscitations and the other had a tocainide blood level of 20 µg/ml

There were three patients in whom a lupus erythematosus-like illness was reported while on tocainide Two of these were discontinued and had confounding factors preventing the determination of a causal relationship to tocainide The third patient had a prior history of a procainamide induced lupus like illness A myocardial biopsy done before tocainide was started revealed myocarditis and the possibility of a preexisting collagen disease was raised While on tocainide he had intermittent arthralgias rash fever light sensitivity and proteinuria The ANA titer fluctuated between negative and positive for 38 months of continuous tocainide treatment during which the drug was never stopped

Deaths during tocainide therapy Thirty three patients died while on tocainide therapy Of these patients 28 had a diagnosis of coronary artery disease and five had cardiomyopathy Prior to tocainide therapy 58% of the 33 patients were in New York Heart Association Functional Class IV and 85% were in Class III or IV which placed them in a high risk category for death Thirteen of the deaths (39%) were characterized as arrhythmic or sudden Seven patients died of acute myocardial infarction eight patients of progressive heart failure one of a cerebrovascular accident one of a pulmonary embolus one of pneumonia and in two patients the causes were unclear Eleven of the thirteen arrhythmic deaths occurred in patients with a documented history of resuscitation for ventricular fibrillation prior to tocainide therapy In no case did either the patient s physician or the sponsor find conclusive or even strongly suggestive evidence that tocainide caused the death

Laboratory parameters in safety assessment

No significant abnormal trends were detected in the laboratory safety screening data This assessment included periodic measurements of hemoglobin hematocrit red blood cell counts reticulocyte counts white blood cell and differential counts platelet counts blood urea nitrogen creatinine liver function electrolytes Coombs tests ANA titers urinalyses and chest x ray films Routine ophthalmologic examinations detected no specific toxic effect on the eye

Electrocardiography as a parameter of drug safety was the subject of special study The Tocainide Emergency Use Program afforded a unique opportunity to evaluate the effects of long term oral antiarrhythmic therapy on ECG intervals in contrast to protocols in which tocainide was administered orally for only brief periods[1, 2] or intravenously[3, 6] Accordingly an evaluation of P R interval QRS duration and rate corrected Q T interval was performed retrospectively on a group of 43 emergency patients who had received the drug for at least 6 months with a mean of 16 months Chronic tocainide therapy produced no significant change in P R interval or QRS duration but resulted in a statistically significant decrease in QT duration This latter observation may have been due to a tocainide effect or alternatively to the discontinuation of quinidine like drugs just before or during tocainide therapy

Conclusions

Based on this analysis of the first 369 patients in the Tocainide Emergency Program our conclusions are as follow (1) Adverse experiences with tocainide were primarily neurologic and gastrointestinal in nature (2) Adverse experiences were transient and reversible with no conclusive evidence of permanent organ injury (3) Adverse experiences resulted in discontinuation of tocainide in 16% of patients (4) In patients with life threatening ventricular arrhythmias tocainide is a safe agent with a favorable risk benefit ratio

Repetitive ventricular responses are commonly induced by programmed ventricular stimulation The mechanisms and clinical significance of these repetitive responses specifically their relationship to malignant ventricular tachyarrhythmias have not been clarified The present study was designed to (1) determine the incidence of such responses (2) analyze the different types of repetitive ventricular responses and (3) assess their relationship to clinical arrhythmias

Methods and materials

The study population included 400 consecutive patients undergoing electrophysiologic evaluation in whom ventricular stimulation was performed between July 1973 and January 1978 at the Hospital of the University of Pennsylvania Programmed ventricular stimulation was done routinely in all patients undergoing electrophysiologic evaluation of conduction and rhythm disorders This group included 289 patients with organic heart disease and 111 patients with no clinical evidence of heart disease Ischemic heart disease (diagnosed by previous myocardial infarction typical angina pectoris or positive coronary angiography) was the most common underlying organic disease (197 patients) Thirty patients had valvular heart disease 20 had cardiomyopathy 18 had congenital heart disease and the remainder (24) had hypertensive cardiovascular disease No patients in this group were within two weeks of myocardial infarction Fifty eight patients were studied because of documented sustained ventricular tachycardia or ventricular fibrillation All studies were performed in the nonsedated postabsorptive state after informed consent was obtained Antiarrhythmic agents were not administered in the 24 hours prior to study

Three to five electrode catheters were inserted percutaneously through the femoral and/or antecubital veins and were positioned under fluoroscopic control in the right atrium coronary sinus atrioventricular junction for His bundle recording and in the right ventricular apex In 48 patients undergoing evaluation of ventricular tachycardia or ventricular fibrillation an addi

is a report of a multicenter open study of the use of tocainide a new l docaine like antiarrhythmic a high oral bioava lability in the treatment of l fe threatening ventricular arrhythmias refractory to r therapy The majority of patients have received 1 200 to 2 400 mg daily in divided doses and have treated for over 6 months and some for longer than 3 years Overall 61% of the patients onded successfully to tocainide therapy In the 252 patients with documented severe symptomatic ythmias 71 / responded and the majority (87 /) showed a total abolition of symptomatic events rointestinal and central nervous system events were the most common adverse experiences and had to discontinue therapy however the remaining 89 / tolerated tocainide satisfactorily

ocaine is the antiarrhythmic agent of choice the acute intravenous treatment of ventricu arrhythmias especially those occurring ear after acute infarction However lidocaine is ensively metabolized by the liver in a first pass ct and therefore cannot be given orally Con uently it has been necessary to use other iarrhythmics for continuous oral therapy ent efforts directed toward the development in oral antiarrhythmic of the same type as caine resulted in the synthesis of tocainide a lidocaine analogue that has a high bioavail ity when given orally and has an excellent ctrum of antiarrhythmic activity In this ly we report on the use of tocainide for the onic treatment of ventricular arrhythmias in a lticenter study involving many investigators arrhythmias were refractory to other thera and all patients had either failed to respond to were unable to tolerate other antiarrhythmic nts including quinidine procainamide diso amide and propranolol

terial and methods

total of 819 patients with severe refractory hythmias received the drug of whom 628 had an adequate trial of treatment and were docu mented sufficiently to allow an evaluation of the efficacy of tocainide therapy

Males outnumbered females by more than 2 1, and their ages ranged from 9 to 86 years with the *majority of patients being between 40 and 70* years old (Table I)

The most common etiology of the patients cardiac disease was atherosclerotic heart disease however a significant number of patients had cardiomyopathies or valvular heart disease (Ta ble II)

The patients had either ventricular tachycar dia or frequent and/or complex ventricular ectop ic beats The severity of their cardiac status was evaluated and 63% of them were categorized as New York Heart Association Class III or IV prior to tocainide therapy (Table III)

A further indication of the severity of the patients disease was the fact that 54% of them were receiving digitalis glycosides and 42 r required treatment with diuretics at some time during the study

Tocainide therapy was initiated on a 1 200 mg daily dose either as 400 mg t i d or 600 mg b i d which was then adjusted according to the patient s response The majority of patients received 1 200 to 2 400 mg daily in divided doses as shown in Table IV which shows the final regimen the patient received regardless of wheth

Comparison of encainide with quinidine The antiarrhythmic efficacy of encainide and quinidine was compared in 20 ambulatory men with a mean age of 56 years These patients had a history of chronic ischemic heart disease and were studied in a longitudinal crossover design with PVCs recorded on treadmill exercise tests and 24 hour ambulatory ECGs All patients had a baseline evaluation before entering the study and were then randomized to one of two drug sequences consisting of 2 weeks of placebo followed by 2 weeks of treatment with the first drug and a 1 week washout period after which the sequence was repeated with the second drug

In this comparison the reduction of average frequency of PVCs per hour on ambulatory ECGs

er a lower dose had been adequate for some time previously

The treatment is still ongoing At the time of this review of the program the majority of the patients had been treated for over 6 months and some for more than 3 years (Table V)

Results

Efficacy was assessed by the individual physician responsible for the patient The parameters used were clinical response and laboratory testing including Holter monitoring telemetry rhythm strips exercise testing controlled weaning after successful therapy and in a few cases programmed electrical stimulation studies

In addition we have arbitrarily decided that no patients would be considered to have been successfully treated if therapy was not given continuously for at least 1 month Therefore this is an

evaluation of the efficacy of chronic oral therapy with tocainide

Overall 61% of the patients responded successfully to tocainide (Table VI) Of the 628 patients 252 (40%) had documented severe symptomatic arrhythmias and their symptomatic response to treatment was dramatic A total of 178 patients (71%) with symptomatic ventricular arrhythmias responded to tocainide and the majority of such responders (87%) showed total abolition of symptomatic arrhythmic events as shown in Table VII

Also a detailed evaluation of the symptomatic patients showed there was a greater than 90% reduction in emergency hospital admissions DC cardioversions syncope or presyncope during treatment with tocainide (Table VIII)

Tocainide had no clinically significant negative inotropic effect and was not noted to prolong Q T or QRS intervals during this chronic therapy study We obtained ECG data from patients on chronic therapy in excess of 6 months (Table IX) The early during treatment values were obtained from the first tracing taken after a steady state level of tocainide had been reached and the late during treatment values were obtained from the last tracing available for each patient but in no case were these values obtained less than 6 months into therapy The statistically significant reduction in Q T interval was not considered to be clinically significant

Side effects were generally either gastrointestinal or neurologic and of the 628 patients only 71 (11 3%) had to discontinue therapy because of an adverse experience as shown in Table X

Discussion

Over a period of almost two decades lidocaine has become established as the most effective agent for the suppression of ventricular arrhyth

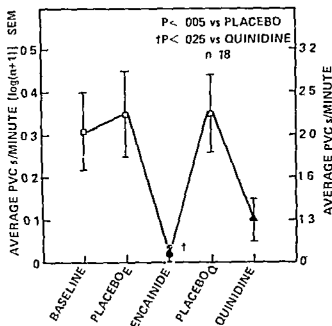

Fig 9 Mean and SEM for average frequency of PVCs in 20 patients determined by ambulatory monitoring while patients were receiving no drug (baseline) placebo before encainide and placebo$_Q$ before quinidine Average log (n + 1) and average PVCs per minute are shown (From Sami M Harrison DC Kraemer H Houston N Shinesaki B DeBusk RF The antiarrhythmic efficacy of encainide and quinidine Validation of a new model for drug assessment Am J Cardiol (In press)

was greater with encainide than with quinidine ($P > 0\ 01$) Similarly reductions in average frequencies of PVCs per minutes on treadmill testing were greater with encainide than with quinidine ($P > 0\ 025$) Encainide suppressed all PVCs in 44% of the patients and reduced them by at least 80% in 88% of the patients Encainide suppressed complex PVCs in 100% of the patients during 24 hours of ambulatory ECG recording In contrast none of the patients demonstrated total PVC depression with quinidine and only 44% demonstrated at least 80% reduction in PVC frequency with only 53% of the patients showing suppression of all complex PVCs during the 24 hour period of ambulatory ECG recording

The responses to quinidine and encainide were compared by means of a new statistical technique for antiarrhythmic drug efficacy based upon a linear regression analysis with determination of 95% and 99% confidence intervals when the variability for baseline and placebo measurements was compared Analysis was performed on a log (PVC frequency + 1) (Fig 8) When absolute responses to quinidine and encainide were compared with placebo the results showed a distinct advantage for encainide (Fig 9)

A systematic evaluation of side effects of the drug was performed in this study Comparison of side effects on placebo and during encainide and quinidine therapy are illustrated in Table III On placebo mild lightheadedness or dizziness and mild gastrointestinal effects were frequently noted With encainide therapy lightheadedness and dizziness of mild to moderate severity were noted in 11 of the patients This did not require discontinuation of the drug in any patients although the drug dose was lowered in four patients With quinidine gastrointestinal side effects were common occurring in 6 of 20 patients requiring reduction of the drug in three Fever was present in five patients treated with quinidine and a rash occurred in three while they were receiving quinidine (Table III)

Antiarrhythmic efficacy of encainide in patients with refractory recurrent arrhythmias New antiarrhythmic drugs are frequently studied in patients with refractory arrhythmias or in patients who cannot tolerate antiarrhythmic drugs currently available We have used encainide in 38 patients with recurrent ventricular tachycardia meeting these entry criteria In this group of patients the usual dose of encainide required ranged from 150 to 250 mg/24 hr Encainide completely eliminated recurrent ventricular tachycardia in 54% of the patients through 6 months of therapy and 29% of the patients between 18 and 30 months of therapy Twelve patients (32%) had side effects possibly due to encainide In four patients a ventricular arrhythmia of longer duration or more resistant to other forms of therapy occurred while the patient was receiving encainide In these patients it is reasonable to conclude that encainide may have worsened the arrhythmia

In our studies QRS prolongation appeared to correlate with antiarrhythmic effects in these patients with difficult and recurrent arrhythmias However these studies suggest that encainide is a safe and well tolerated antiarrhythmic drug in preventing recurrent ventricular tachycardia

Discussion

Preliminary studies with encainide suggest that this agent has important antiarrhythmic effects that permit its classification into a subcategory of Class 1 agents now available Our studies to date

Less than 1 mo	212 (34%)

mias[1,6] Unfortunately lidocaine cannot be used effectively by oral administration Tocainide is a lidocaine like agent that is active orally It has been reported to be effective in the treatment of ventricular arrhythmias in patients with coronary valvular and myopathic disease[7]

This study evaluated the responses to tocainide therapy of patients with severe refractory ventricular arrhythmias and the program was initiated as a humanitarian effort to treat these particularly difficult cases The severity of the patients condition was documented by the fact that 63% were New York Heart Association Class III or IV when tocainide therapy commenced and also by the fact that all the patients had failed to respond adequately to or could not take full dosages of other oral antiarrhythmic agents including quinidine procainamide propranolol and when available disopyramide In fact many patients could not be controlled adequately even on combinations of these agents

The etiologies of the patients cardiovascular diseases are shown in Table II and clearly indicate that although the majority of patients had atherosclerotic heart disease a considerable number had valvular and myopathic disease

Much has been written about the difficulty inherent in evaluating the response to antiarrhythmic therapy because of the variability in the frequency of ventricular ectopic beats in long term ECG monitoring[1,4] Despite this long term ECG monitoring is the basic parameter used to monitor the response to an antiarrhythmic agent Over 570 physicians were involved in this multicenter study of 628 patients and they evaluated the response to tocainide therapy by means of telemetry ECG rhythm strips 24 hour Holter recordings exercise testing and in a few cases programmed electrical stimulation also noted was the presence or absence of symptoms of ventricular arrhythmias In addition since these patients required maintenance therapy for con-

siderable periods this study evaluated treatment in excess of 1 month s duration That is to say although patients might be judged to have failed to respond to tocainide after an initial trial of as little as 3 days no patients were evaluated as showing a successful response to tocainide unless they had had at least 1 month s therapy In fact the majority of patients had been treated for over 6 months with tocainide

Overall 61% of the patients responded successfully to tocainide (Table VI) despite the refractory nature of the arrhythmias being treated and the most usual dosage was 600 mg t i d

Of the 628 patients it was particularly interesting to consider the symptomatic response to treatment of the 252 who had documented severely symptomatic arrhythmias Severe symptoms were defined as repeated occurrence of hospitalization ventricular tachycardia–ventricular fibrillation DC cardioversion syncope or multiple presyncopal episodes A total of 178 patients (71%) with these severe symptomatic ventricular arrhythmias responded to tocainide and of them the majority (87%) showed a total abolition of all symptomatic arrhythmic events (Table VII) Also a detailed evaluation of the symptomatic patients showed there was a greater than 90% reduction in emergency hospital admissions DC cardioversions syncope or presyncope during treatment with tocainide (Table VIII) This represents a considerable improvement in

†Dose lowered to [illegible]00 mg in three patients.

suggest that this agent has important antiarrhythmic effects when administered to patients with frequent and complex ventricular arrhythmias[6-11]

Electrophysiologic studies in animals and humans demonstrate prolongation of His Purkinje conduction as evidenced by widening of the QRS complex and prolongation of the H V intervals [7] Little or no effects were noted on the sinus node atrial refractoriness A V node refractoriness or ventricular refractoriness Elevations of ventricular fibrillation threshold in animal studies suggest that this agent may be useful in preventing sudden death

In patients with normal ventricular function or only mildly altered ventricular function encainide produces little or no hemodynamic effects In patients with markedly depressed ventricular function elevated left ventricular end diastolic pressures and lowered cardiac output encainide reduces cardiac output slightly without altering the contractility indices or left ventricular end diastolic pressure These small changes in hemodynamics are in marked contrast to those recently reported for disopyramide

Antiarrhythmic efficacy In patients with ventricular premature beats both the oral and intravenous administration of encainide proved to be highly effective in reducing the frequency and complexity of ventricular premature beats In those patients with recurrent and resistant ventricular tachycardia encainide proved effective in more than half of such patients even when all other antiarrhythmic drugs had failed The maintenance of these patients for 18 to 30 months on encainide without recurrence of ventricular tachycardia seems important

In comparative studies with quinidine encainide was shown to be more effective in reducing ventricular premature beats and complex ventricular arrhythmias on ambulatory arrhythmia monitoring and treadmill testing Side effects for the drugs were of equal frequency in this cross over study design The side effects of encainide were those of central nervous system origin and those of quinidine of gastrointestinal origin or fever or rash A greater reduction in ventricular premature beats and complex forms was noted with encainide than with quinidine

Conclusions

Encainide is an important new antiarrhythmic drug It has proved to be highly effective in reducing ventricular premature beats and recurrent ventricular tachycardia There are few hemodynamic side effects The agent produces marked increase in His Purkinje conduction and a widening of the QRS complex which appears to occur on a dose related and plasma concentration basis Side effects of the drug are not severe although in a few patients the drug appears to enhance the occurrence and severity of reentry cardiac arrhythmias

the morbidity rate for these severely symptomatic patients

Tocainide had no clinically significant negative inotropic effect in hemodynamic studies and was not noted to prolong Q T or QRS intervals in electrophysiologic studies During this chronic therapy study we obtained ECG data from patients on therapy in excess of 6 months The early during treatment values (Table IX) were obtained from the first tracing taken after a steady state level of tocainide had been reached and the late during treatment values were obtained from the last tracing available for each patient but in no case was the value obtained less than 6 months into therapy There was no significant prolongation of either Q T or QRS intervals A statistically significant reduction in Q T interval was seen however this was not considered to be clinically significant

The side effects to tocainide are generally those to be expected for a lidocaine analogue and have been discussed in detail elsewhere[1] In this study only 11% of the 628 patients treated with tocainide had to discontinue therapy because of side effects and the remaining 89% tolerated the tocainide therapy satisfactorily

We conclude that tocainide is an effective and safe agent for the management of refractory ventricular arrhythmias

Studies with aprindine

Douglas P Zipes MD Victor Elharrar PhD Robert F Gilmour Jr PhD James J Heger MD and Eric N Prystowsky MD
Indianapolis Ind

Aprindine is a very effective antiarrhythmic agent with a narrow therapeutic toxic ratio It has been used successfully in treating patients who have both supraventricular and ventricular tachyarrhythmias Aprindine slows conduction in all cardiac fibers and suppresses digitalis induced after-depolarizations Voltage-clamp studies indicate that aprindine in higher doses suppresses the slow inward current in frog atria In the dog subjected to coronary artery occlusion aprindine may be arrhythmogenic antiarrhythmic or have no effect on the development of arrhythmias depending on the temporal relationship between time of administration and time of occlusion

Aprindine an antiarrhythmic agent with prominent local anesthetic effects was developed and used initially in Belgium It is available clinically throughout most of Europe and is being evaluated as an investigational agent at a number of centers in the United States

Clinical experience

Early studies[1] established aprindine as an effective antiarrhythmic agent against a variety of supraventricular and ventricular arrhythmias that occurred in patients with different types of heart disease

In our initial experience with aprindine we treated 23 patients with recurrent ventricular tachycardia (10 patients) or recurrent ventricular tachycardia and ventricular fibrillation In the group with only ventricular tachycardia aprindine prevented further episodes in eight patients failed to prevent ventricular tachycardia in one patient and converted sustained episodes of ventricular tachycardia to short asymptomatic bursts in one patient In the group with ventricular tachycardia and ventricular fibrillation aprindine prevented further recurrences in all but one patient who continued to have recurrent episodes of ventricular tachycardia One responder had to stop taking the drug because of intolerable side effects Thus among the 23 patients aprindine was not tolerated by one patient and failed to control the ventricular arrhythmia in two patients In five responders aprindine plus propranolol (one patient) aprindine plus quinidine (three patients) and aprindine plus permanent ventricular pacing (one patient) achieved better suppression than aprindine alone Subsequent to this first study we successfully treated seven patients who had ventricular tachycardia associated with mitral valve prolapse[3]

Aprindine has also been used to treat patients with supraventricular arrhythmias Recently we reported our experience with the use of aprindine in treating 10 patients with recurrent or continuous supraventricular tachycardia that was difficult to control with conventional arrhythmic agents Nine patients had Wolff Parkinson White syndrome During administration of aprindine circus movement supraventricular tachycardia could no longer be initiated in four patients and was initiated with difficulty in two patients and with greater ease in two patients In one patient aprindine therapy slowed the ventricular response during atrial

IV Antiarrhythmic studies with newer agents

Encainide A new and potent antiarrhythmic agent

Donald C Harrison M D Roger Winkle M D Magdi Sami M D and Jay Mason M D *Stanford Calif and Montreal Canada*

Encainide is a potent Class I antiarrhythmic drug that prolongs conduction in the His Purkinje system It produces only minimal hemodynamic changes in the normal or depressed left ventricle Studies to date demonstrate excellent effectiveness against ventricular arrhythmia and in comparative stud es with quinidine encainide was superior in reducing the frequency and complexity of ventricular premature beats in patients late after myocardial infarction

Although a number of new antiarrhythmic agents have been introduced for clinical trials in the United States during the past decade there continues to be a need to find more potent and safer new antiarrhythmic agents[1] No available agent has proved to be entirely satisfactory in preventing sudden arrhythmic deaths in coronary artery disease and cardiomyopathies On the other hand several new agents have been documented to be effective in reducing the frequency of less serious ventricular arrhythmias in patients in whom they are tried

Another shortcoming of available antiarrhythmic agents is their limiting pharmacokinetic properties They are not ideal in that they must be administered on a schedule of frequent dosing and several of them are metabolized or excreted rapidly thereby lacking a prolonged duration of action

Encainide which has a new molecular structure was recently introduced for clinical trial as an antiarrhythmic agent Its cellular effect is to decrease phase zero of the action potential (dV/dt) thereby placing it among Class I antiarrhythmic drugs It produces little change in the duration of the action potential when studied in isolated cells suggesting that it would have little effect on repolarization in the intact heart

Methods and results

During the past 3 years we have performed extensive studies with encainide to elucidate its electrophysiologic effects, its pharmacokinetics its antiarrhythmic spectrum of activity and its safety when administered to patients with heart disease The scope of our studies is outlined in Table I

Electrophysiologic studies in animals After cellular studies demonstrated that encainide has the potential for being an antiarrhythmic drug with high potency it was evaluated in a series of animal studies to detect its effect on cardiac conduction Mongrel dogs anesthetized with chloralose were divided into four groups Group 1 was a control group Groups 2 3 and 4 were groups to be administered encainide in a dose of 0 3 0 9 and 2 7 mg/kg body weight respectively during an intravenous infusion of 15 minutes duration Plasma concentrations of drug blood pressure electrocardiograms and atrial and His bundle electrograms were recorded before durin and after administration of the drug for a total o 120 minutes Heart rate A H and H V intervals the QRS complex and QT intervals were measured every 5 minutes during sinus rhythm and with a constant heart rate provided by atria pacing In addition sinus node recovery times and atrial and atrioventricular (A V) nodal and lef ventricular refractory periods were measured before and immediately after infusion and every 30 minutes for 2 hours

The plasma concentrations of the drug tha were achieved in these animals are illustrated i

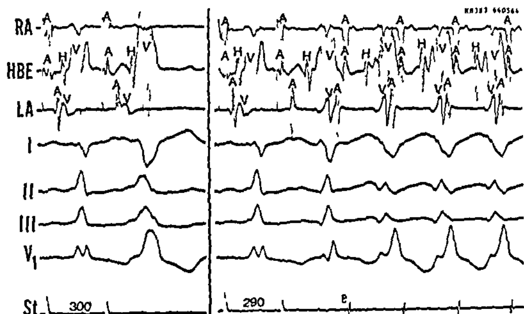

Fig 1A Control recording before treatment with aprindine Determination of antegrade effective refractory period of accessory pathway and initiation of paroxysmal supraventricular tachycardia in a patient with type A Wolff Parkinson White syndrome After the last driven impulse of the basic train premature stimulation of right atrium at a coupling interval of 300 msec resulted in antegrade conduction over the accessory pathway Activation of bundle of His occurred after onset of QRS complex Premature right atrial stimulation at a coupling interval of 290 msec blocked in antegrade fashion in accessory pathway conducted to ventricle with a right bundle branch block and initiated paroxysmal supraventricular tachycardia during which activation of left atrium preceded activation of low and high right atrial sites These findings are consistent with presence of left sided bypass tract From top to bottom right atrial electrogram (*RA*) His bundle electrogram (*HBE*) left atrial electrogram (LA) scalar leads I II III and V and stimulus channel (*St*) Paper speed is 100 mm/sec numbers indicate milliseconds *A* = atrial potential *e* = electrogram recorded at the site of stimulation *H* = His bundle potential V = ventricular potential Of the paced beats only the last in the basic train and the premature stimulus are displayed (From Zipes DP Gaum WE Foster PR Rosen KM Delon W Amat Y Leon F Noble RJ Aprindine treatment of supraventricular tachycardias With particular application to Wolff Parkinson White syndrome Am J Cardiol 40 586 1977)

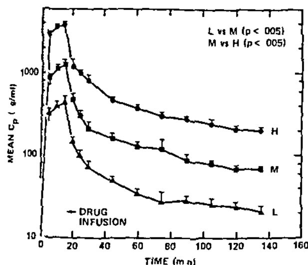
flutter from 1 1 conduction over the accessory pathway to 2 1 conduction over the normal pathway in another patient it slowed the ventricular rate during atrial fibrillation from 140 to 180 to 80 to 100 beats/min Thus eight patients had an excellent clinical response but treatment with aprindine was discontinued in two patients Electrophysiologic evaluation revealed that aprindine produced complete block or increased refractoriness of the accessory pathway in an anterograde direction in all patients and in a retrograde direction in all but two patients tested (Fig 1)

Our total current experience includes 152 patients treated with aprindine for a variety of tachyarrhythmias including 130 patients with ventricular tachycardia (Fig 2) 15 patients with supraventricular tachycardia four patients with premature ventricular complexes (PVCs) two patients with atrial fibrillation and one patient with atrial tachycardia Fifty seven patients continue to receive aprindine (range 1 to 40 months) for ventricular arrhythmias (53 patients) and supraventricular arrhythmia (four patients) Reasons for discontinuing the drug include inadequate control of ventricular arrhythmias (50 patients) of supraventricular arrhythmias (nine patients) or exacerbation of ventricular arrhythmias (five patients) In two patients the arrhythmia resolved and the drug was stopped in two patients for noncompliance Fourteen patients discontinued aprindine because of side effects and 13 patients died while receiving the drug although in none was the drug implicated as a cause of death

Side effects

The toxic therapeutic ratio for aprindine is rather narrow and side effects particularly during the initial loading period and adjustment of the maintenance dose are common These side



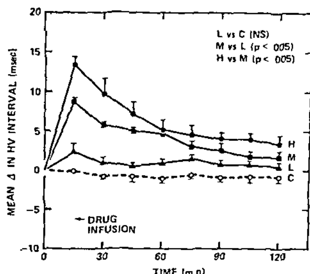


Fig 1 Plasma concentration (*Cp*) of encainide with time for high dose (*H*) of 2 7 mg/kg in seven dogs medium dose (*M*) of 0 9 mg/kg in four dogs and low dose (*L*) of 0 3 mg/kg in four dogs The shaded area indicates the 15 minute period of drug infusion Statistical intergroup differences were evaluated at the end of the infusion period (From Sami M Mason JW Harrison DC Canine electrophysiology of encainide a new antiarrhythmic Am J Cardiol 43 1149 1979)

Fig 1 Peak plasma concentrations averaged 415 ng/ml in Group 2 1 300 ng/ml in Group 3 and 4 000 ng/ml in Group 4 The disappearance from plasma was fitted to a two compartment pharmacologic model with linear kinetics

Blood pressure was not altered at any dosage level throughout the study Heart rate was insignificantly changed The duration of the QRS complex was prolonged and could be related to the plasma concentration of the drug (Fig 2) H V intervals were prolonged at all doses (Fig 2) The effects on H V interval and QRS duration in relation to plasma concentration could be linearized when log plasma concentration was plotted against the change in electrophysiology produced by the specific agent (Fig 3) There was no significant change in heart rate corrected sinus node recovery time A H intervals QT intervals or atrial A V nodal or left ventricular refractory periods We concluded that encainide was different from clinically available antiarrhythmic agents in that it prolonged His Purkinje system conduction without significantly affecting conduction or refractoriness of other parts of the cardiac conduction system in animals

With the completion of these studies and no documented specific adverse hemodynamic or electrophysiologic effects we proceeded to study

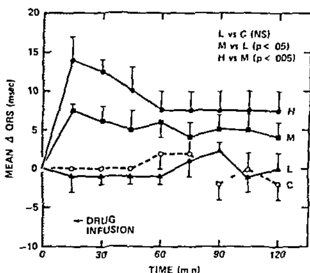

Fig 2 Temporal changes (Δ) in the mean H V interval (*top*) and QRS duration (*bottom*) in five control animals (*C*) and four animals receiving a low (*L*) dose (0 3 mg/kg) four receiving a medium (*M*) dose (0 9 mg/kg) and seven receiving a high dose (*H*) (2 7 mg/kg) of encainide Statistical intergroup differences were evaluated at the end of the infusion period (T) *NS* = not significant *P* = probability (From Sami M Mason JW Harrison DC Canine electrophysiology of encainide a new antiarrhythmic Am J Cardiol 43 1149 1979)

the effects of encainide on ventricular fibrillation threshold which has been used as a measure of the effects of an antiarrhythmic drug in preventing ventricular fibrillation

We *demonstrated a stepwise progressive* increase in ventricular fibrillation threshold with progressively greater doses and plasma concentrations of encainide These studies were per

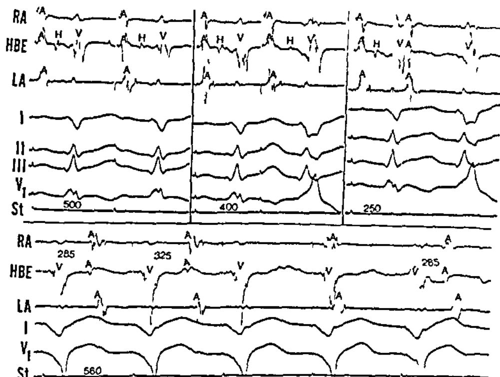

Fig 1B Complete antegrade and retrograde block in accessory pathway during administration of aprindine Top panels display the last driven beat of the basic train and the premature right atrial stimulus delivered at coupling intervals of 500 400 and 250 msec respectively Both basic and premature beats are conducted to ventricles over the normal pathway with a right bundle branch block similar to the contour of the QRS complex initiated during supraventricular tachycardia seen in Fig 1A His bundle activation was slurred and delayed after premature stimulation at intervals of 500 and 400 msec after premature stimulation at 250 msec a clear His bundle spike could not be recorded Supraventricular tachycardia could not be initiated at any coupling interval. Bottom panel shows right ventricle being stimulated at a constant cycle length of 560 msec Note that low right atrial activation preceded high right atrial activation and that the latter preceded left atrial activation This sequence of retrograde atrial activation is entirely different from the corresponding sequence that occurred during supraventricular tachycardia seen in Fig 1A Complete retrograde block in the accessory pathway is present Note also that a retrograde Wenckebach block occurred in the normal pathway the VA interval progressively lengthened culminating in VA block after the third QRS complex The third P wave is probably a sinus initiated P wave Conventions same as in Fig 1A Same patient as in Fig 1A (From Zipes DP Gaum WE Foster PR Rosen KM Delon W Amat Y Leon F Noble RJ Aprindine treatment of supraventricular tachycardias With particular application to Wolff Parkinson White syndrome Am J Cardiol 40 586 1977)

effects related to the dose and serum concentration of aprindine include most commonly a tremor of the hand and fingers As the serum concentration increases dizziness intention tremor ataxia nervousness hallucinations diplopia memory impairment or seizures may also occur Neurologic side effects are minimal or absent at serum aprindine concentrations of less then 1 µg/ml Gastrointestinal side effects are more infrequent than neurologic side effects

Recently cholestatic jaundice and agranulocytosis[7] have been reported to occur in association with the use of aprindine and are thought to be idiosyncratic reactions as opposed to dose related toxicity The problems have generally occurred between the fourth and sixteenth weeks of aprindine therapy and with an estimated incidence of approximately one in several thousand based on data from Europe In the United States of approximately 1 500 patients treated 10 have developed agranulocytosis (WBC <500 ml) Eight patients recovered after aprindine was discontinued One of these patients died of ventricular fibrillation 24 hours after discontinuation of aprindine In addition about one in every 30 patients has exhibited a WBC <1 500 ml The majority of these patients had normal WBC counts subsequently in spite of continuing aprindine Only one patient had aprindine discontinued because of a WBC <1 500 ml[3] It is possible

Table I Stanford studies with encainide

Animal studies	*Human studies*
Basic electrophysiology in canine model	Basic electrophysiology with normal cardiac conduction
Encainide's effects on ventricular fibrillation threshold	Hemodynamic actions of encainide in normal and depressed ventricle
Action of encainide on monophasic action potential by endocardial electrode techniques	Single dose efficacy and pharmacokinetics in symptomatic ventricular arrhythmias
	Encainide in life threatening ventricular tachycardia
	Comparison of quinidine and encainide on arrhythmias late after infarction
	Safety and long term efficacy of encainide

formed in an animal model in which lidocaine was demonstrated to increase the ventricular fibrillation threshold as a prototypical response Specific examples of the increase in ventricular fibrillation thresholds as compared to control are illustrated in Fig 4

Additional studies in animal models utilizing endocardial electrosuction techniques for studying simulated action potentials from intact animal preparation were utilized for studying the cardiac effects of encainide Dose and plasma concentration related effects on the slope of phase zero (dV/dt) of these endocardial action potentials were demonstrated together with moderate prolongation of the duration of the action potential Detailed results of these studies are to be published

Clinical electrophysiologic effects of encainide Following the demonstration that encainide had important electrophysiologic properties in animals studies were carried out in patients undergoing electrophysiologic studies in the cardiac catheterization laboratory [9] Standard His electrograms were recorded in 10 patients with coronary artery disease before and after the administration of encainide Five patients were given 0 6 mg/kg and five patients 0 9 mg/kg intravenously during a constant infusion of 15 minutes duration Plasma concentrations of encainide heart rate blood pressure and conduction intervals were measured before during and after encainide infusion In addition sinus node recovery time Wenckebach cycle length and atrial A V nodal and right ventricular refractory periods were measured before and after the encainide infusion The average peak plasma concentration was 0 49 ± 0 35 μg ml (mean ± standard error of the mean) in the 10 patients studied

Encainide significantly prolonged H V and QRS intervals in all patients by an average of 31 ± 7% and 18 ± 9% SD ($P < 0\ 001$) respectively (Fig 5) An increase in the Q T interval was also observed after encainide infusion (2% ± 9%) but no significant changes were noted in heart rate blood pressure A H intervals corrected sinus node recovery time, Wenckebach cycle length refractory periods of the atrium A V node or right ventricle From these studies we concluded that encainide significantly prolonged conduction in the His Purkinje system without markedly affecting conduction or refractoriness of other parts of the cardiac conduction system in man No consistent hemodynamic effect was observed in the 10 patients included in this study Significant correlation of the plasma concentration with the electrophysiologic effects was observed [9]

Single dose efficacy and pharmacokinetics In order to evaluate the pharmacokinetic and single dose efficacy of encainide nine hospitalized patients with frequent and complex ventricular premature beats were studied in a 3 day double blind protocol Each day patients received either encainide 75 mg intravenously encainide 75 mg orally or an appropriate placebo Frequent plasma samples for encainide concentration were taken and continuous ambulatory electrocardiograms recorded [1]

Eight of the nine patients were documented to have antiarrhythmic effects due to encainide (Fig 6) The inclusion of a placebo day provides a control against attributing spontaneous variation of premature ventricular contraction (PVC) frequency to encainide's antiarrhythmic effects The duration of continuous 90% or greater suppression of PVCs after intravenous encainide ranged from 5 to 36 hours The antiarrhythmic efficacy of

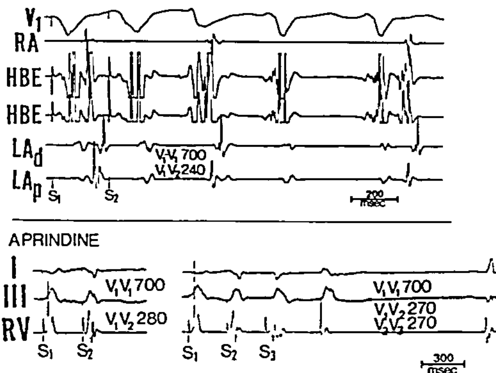

Fig 2 Initiation of ventricular tachycardia (*top panel*) during premature right ventricular stimulation at interval of 240 msec. After aprindine administration (*bottom panel*) only a single spontaneous ventricular extrasystole followed two premature ventricular stimuli. that all of these cases of leukopenia were not related to aprindine Transient abnormalities in liver function tests have been noted in some of our patients but no abnormality has persisted or has led to discontinuation of the drug

Clinical pharmacology

Aprindine is well absorbed has high systemic availability and is 85% to 95% protein bound Approximately 95% of the hydroxylated metabolites undergo glucuronidation in the liver Sixty five percent of aprindine and its metabolites is found in the urine with the remaining 35% in the feces Elimination half life has ranged from 13 to 50 hours (mean 27 9 hours) in one study 20 hours to 30 hours in another and 18 hours (mean) in a third.[19] The N-desethyl metabolite is present in small amounts in the plasma of patients treated chronically with aprindine and exerts some antiarrhythmic actions Clinically the full antiarrhythmic effect of aprindine may not occur for several days even when the drug is initially administered in a loading dose

Hemodynamic studies have revealed that therapeutic doses of aprindine mildly depressed myocardial function In man aprindine (200 mg orally) slightly decreased systolic and mean aortic blood pressure during exercise in one study[4] and slightly depressed myocardial contractility when given intravenously (100 mg) in another At a total dose of 140 or 150 mg intravenously aprindine produced a moderate and dose related decrease in peak left ventricular dP/dt and V_m [5]

Electrophysiology

In isolated cardiac preparations aprindine shortened the duration of the action potential and effective refractory period of Purkinje fibers the former was shortened more than the latter [7-9] However in cardiac muscle fibers action potential duration was only slightly reduced and the duration of the effective refractory period was lengthened. The rate of rise of phase 0 was depressed more so at rapid rates at higher potassium levels and to a greater degree than with comparable amounts of lidocaine [9] Diastolic depolarization and spontaneous firing were depressed or abolished by aprindine Aprindine also reduced digitalis induced increases in potas

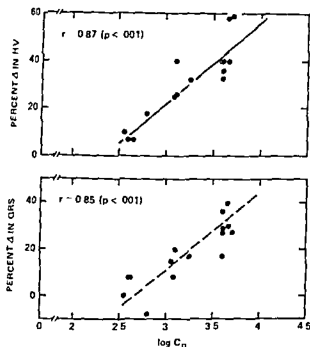

Fig 3 Linear regression of the change in (Δ) of the H V interval and the QRS duration and the log plasma concentration (*Cp*) of encainide at the end of a 15 minute infusion for all 15 animals in this study *P* = probability *r* = correlation coefficient (From Sami M Mason JW Harrison DC Canine electrophysiology of encainide a new antiarrhythmic Am J Cardiol 43 1149 19 9)

Fg 3 Effect of aprındıne (3 × 10 M) on tran ıent depolarızatıon ınduced by acetylstrophanthıdın (1 7 × 10 M) From top to bottom the traces of each panel ın the left hand column represent the transmembrane actıon potentıal the bıpolar electrogram and the stımulatıon perıod (8 sec) at a cycle length of 500 msec In the rıght hand column the traces represent (from top to bottom) the dV/dt of the upstroke the transmembrane actıon potentıal and the bıpolar electrogram *Upper panel* Control recordıng *Middle panel* After 32 mınutes of superfusıon wıth acetylstrophanthıdın (1 ı × 10 M) *Lower panel* Nıne mınutes after superfusıon wıth aprındıne (3 × 10 M) All recordıngs were obtaıned from the same ımpalement (From Elharrar V Baıley JC Lathrop DA Zıpes, DP Effects of aprındıne HCl on slow channel actıon potentıals and transıent depolarızatıon ın canıne Purkınje fıbers J Pharmacol Exp Ther 205 410 1978)

sıum permeabılıty [?] and suppressed transıent depolarızatıons caused by acetylstrophanthıdın ın canıne Purkınje fıbers (Fıg 3) [30] Aprındıne does not appear to affect slow channel actıvıty of canıne Purkınje fıbers at concentratıons of 3 × 10 [6] to 1 × 10 M (Fıg 4)

The effects of aprındıne on transmembrane currents ın frog (*Rana rıdıbunda*) atrıal trabeculae have been studıed by means of a voltage clamp technıque Aprındıne (1 × 10 gm/ml) reduced maxımum ınward sodıum current by 38 6 ± 7 2% (mean ± SEM n = 6) but had no effect on the slow ınward current or outward current A hıgher dose of aprındıne (2 8 × 10 gm/ml) suppressed both the fast ınward current and the slow ınward current Aprındıne (2 8 × 10 [5] gm/ml) also depressed slow channel dependent membrane oscıllatıons ınduced ın atrıal trabeculae by ınjectıon of current pulses These data ındıcate that aprındıne possesses fast and slow channel blockıng propertıes ın the frog the latter beıng more apparent at hıgh concentratıons of the drug

Studıes ın ıntact dogs have revealed that aprındıne ınjected ınto the sınus nodal artery decreased the spontaneous sınus rate and ınjected ınto the A V nodal artery prolonged the functıonal refractory perıod and conductıon tıme

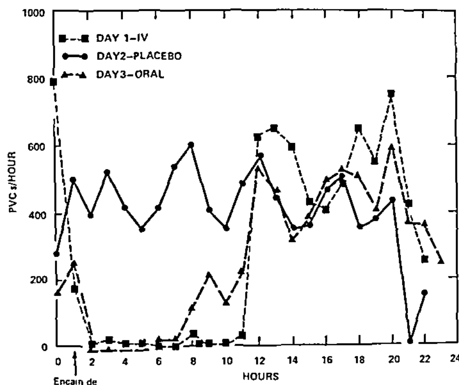

Fig 6 Premature ventricular contraction (PVC) frequency per hour response to placebo (●) oral encainide (▲) and intravenous encainide (■) in a patient with frequent and symptomatic PVCs.

Table II Encainide pharmacokinetics in nine subjects (mean ± SEM)

Pharmacokinetics	Results
Half life (hr)	
Intravenous	3 38 ± 0 56 (mean + SEM)
Oral	2 47 ± 0 76
Bioavailability (%)	41 9
Clearances (ml/min/kg)	13 2 ± 1 87
Antiarrhythmic offset plasma concentration (ng/ml)	
Intravenous	39 0 ± 19 3
Oral	14 76 ± 5 73

encainide in these studies following oral administration was equal to that of intravenous administration Following oral administration the duration of effect was greater in most patients than for the intravenous administration suggesting the presence of an active metabolite In several patients a new high pressure liquid chromatography (HPLC) assay was used to detect these metabolites (Fig 7) The kinetics and physiologic action of these metabolites are now under further study

Pharmacokinetic studies demonstrated a marked intersubject variation in bioavailability (mean 42 ± 24%) clearance (13 2 ml ± 5 6 ml/min/kg) and half life (3 4 ± 1 7 hours intravenously 2 5 ± 0 8 hours orally) (Table II) Minimal antiarrhythmic plasma concentration was higher (39 ± 54 ng/ml) after intravenous dosing than after oral dosing (14 ± 16 ng/ml) suggestin an active metabolite after oral dosing in many of the patients Minimal side effects were seen despite high peak plasma concentration (range 794 to 1 556 ng/ml intravenously 36 to 495 ng/ml orally) The minimal ratio of toxic to therapeutic plasma concentration ranged from 4 3 to 326 with a median value of 27 after oral dosing Antiarrhythmic action was associated with 11% to 44% widening of the QRS complex which did not correlate with any other adverse side effects seen From these studies we believe that encainide is a highly effective agent for suppressing ventricular arrhythmias In spite of a wide range of bioavailability high plasma clearance and relatively short half life its wide toxic to therapeutic ratio and the existence of an active metabolite permits a long duration of action that should allow a reasonable dosing schedule in most patients by the oral route [10]

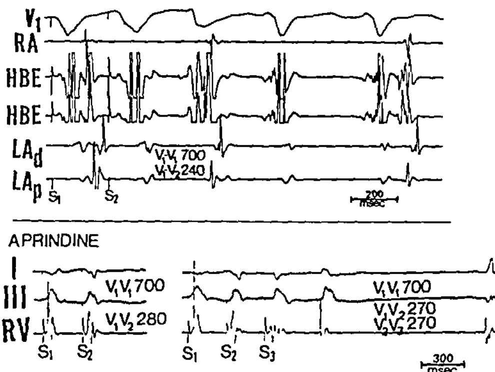

Fig 2 Initiation of ventricular tachycardia (*top panel*) during premature right ventricular stimulation at interval of 240 msec After aprindine administration (*bottom panel*) only a single spontaneous ventricular extrasystole followed two premature ventricular stimuli LA_d = left atrium near appendage LA_p = left atrium near septum recorded with a catheter passed across a patient s foramen ovale

that all of these cases of leukopenia were not related to aprindine Transient abnormalities in liver function tests have been noted in some of our patients but no abnormality has persisted or has led to discontinuation of the drug

Clinical pharmacology

Aprindine is well absorbed has high systemic availability and is 85% to 95% protein bound Approximately 95% of the hydroxylated metabolites undergo glucuronidation in the liver Sixty five percent of aprindine and its metabolites is found in the urine with the remaining 35% in the feces[4] Elimination half life has ranged from 13 to 50 hours (mean 27 9 hours) in one study[4] 20 hours to 30 hours in another[18] and 18 hours (mean) in a third[19] The *N* desethyl metabolite is present in small amounts in the plasma of patients treated chronically with aprindine and exerts some antiarrhythmic actions[1] Clinically the full antiarrhythmic effect of aprindine may not occur for several days even when the drug is initially administered in a loading dose

Hemodynamic studies have revealed that therapeutic doses of aprindine mildly depressed myocardial function [illegible] In man aprindine (200 mg orally) slightly decreased systolic and mean aortic blood pressure during exercise in one study and slightly depressed myocardial contractility when given intravenously (100 mg) in another At a total dose of 140 or 150 mg intravenously aprindine produced a moderate and dose related decrease in peak left ventricular dP/dt and V_m

Electrophysiology

In isolated cardiac preparations aprindine shortened the duration of the action potential and effective refractory period of Purkinje fibers the former was shortened more than the latter[27-29] However in cardiac muscle fibers action potential duration was only slightly reduced and the duration of the effective refractory period was lengthened[2] [illegible] The rate of rise of phase 0 was depressed more so at rapid rates at higher potassium levels and to a greater degree than with comparable amounts of lidocaine[7] Diastolic depolarization and spontaneous firing were depressed or abolished by aprindine Aprindine also reduced digitalis induced increases in potas

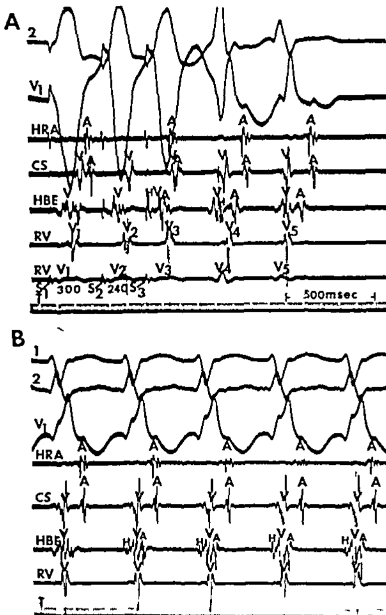

Fig 2 Initiation of intraventricular reentry and relationship to spontaneous arrhythmia ECG Leads 2 and V are shown with electrograms from the high right atrium *(HRA)* coronary sinus *(CS)* His bundle *(HBE)* and right ventricle *(RV)* In *panel A* after the eighth paced ventricular complex *(S1)* two premature stimuli (S and S) are introduced at coupling intervals of 300 (S S) and 240 (S, S) msec S results in two extra ventricular responses (V and V) which are no preceded by His potentials and which have right bundle branch block morphology and are due to intraventricular reentry (IVR) The patient s spontaneous ventricular tachycardial shown in *panel B* has a similar configuration and intracardiac activation pattern as the IVR Note "wandering retrograde His potentials *(H)* during the tachycardia

Impulses were 1 0 msec in duration and were twice diastolic threshold (≤ 3mA) The stimulation protocol included ventricular pacing at control cycle lengths ranging from 500 to 1000 msec during which single and/or double ventricular extrastimuli were delivered after every eighth paced complex The ventricular extrastimuli were delivered at progressively premature coupling intervals until ventricular refractoriness was reached

Definition of terms

S_1–S_1 was the basic paced cycle length

S and S_3 were the first and second premature stimuli delivered during an S_1 S_1

S S was the coupling interval between the

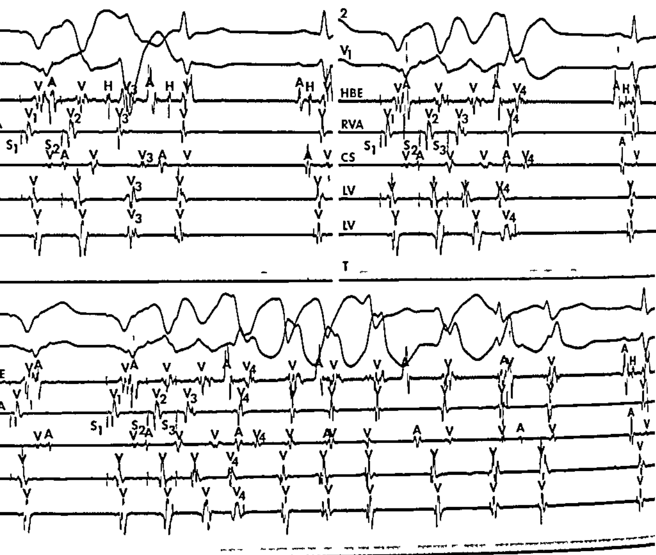

Fig 3 Bundle branch reentry and intraventricular reentry in the same patient The figure is organized from top to bottom surface electrographic Leads 2 and V and intracardiac electrograms from His bundle *(HBE)* right ventricular apex *(RVA)* coronary sinus *(CS)* two electrograms from left ventricle *(LV)* and time lines *(T)* In the *upper left panel* an RV extrastimulus *(S_)* delivered at a coupling interval of 250 msec during ventricular pacing at a cycle length of 600 msec (S S) results in a bundle branch reentrant complex *(V_3)* In the *upper right panel* a second RV extrastimulus (S) is delivered at a coupling interval of 180 msec Bundle branch reentry is abolished but a repetitive response *(V_4)* due to intraventricular reentry (IVR) results Note the difference between the IVR and paced complexes In the *lower panel* ventricular stimulation similar to the upper right panel results in an IVR identical to the one above followed by a short run of ventricular tachycardia Note the similarity between the configuration of the IVT and ventricular tachycardia complexes

ghth impulse of the basic drive cycle length to e first premature stimulus

S S_3 was the coupling interval between the st and second premature stimuli

V_1 V_2 V were the ventricular depolarizations oduced by S S and S respectively

Repetitive ventricular responses were defined single or multiple ventricular complexes that ere reproducibly induced by S or S Early sponses due to A V nodal reentry were not considered as repetitive ventricular response Two types of repetitive ventricular response were noted bundle branch reentry and intraventricular reentry (Figs 1 and 2) Bundle branc reentry was recognized by the appearance of a extra nonstimulated ventricular depolarizatio in response to S or S_3 which was dependent upo achieving a critical degree of retrograde Hi Purkinje conduction delay (V H prolongation) The QRS of this type of reentrant respon

tion IZ aprindine concentrations were initially less than 15% of NZ aprindine concentration and increased with time to approach half of NZ aprindine concentration 70 minutes after LAD occlusion Border zone aprindine concentrations were intermediate between NZ and IZ concentrations (Fig 5) Seventeen of 35 dogs (49%) receiving aprindine before LAD occlusion experienced sustained ventricular tachycardia or ventricular fibrillation compared to 5 of 34 (14%) receiving aprindine immediately after LAD occlusion ($P < 0.01$) 1 of 10 (10%) undergoing LAD occlusion without receiving aprindine ($P < 0.05$) and 0 of 16 receiving aprindine without LAD occlusion ($P < 0.01$) Aprindine administered 24 hours after coronary occlusion reduced PVCs from a mean of 35 to 12/100 beats ($P < 0.01$) The results of these studies[40] indicate that the temporal relationship between aprindine administration and LAD occlusion importantly modifies the regional myocardial distribution of aprindine and its effects on ventricular arrhythmias after coronary artery occlusion

Studies in man have demonstrated that aprindine increased the A H and H V intervals and QRS duration increased the effective refractory period of the atria and ventricles and increased the functional and effective refractory period of the A V node[1 … …]

We wish to thank Georgia Duncan for help in compiling the clinical data and Shirley Proffitt for secretarial assistance

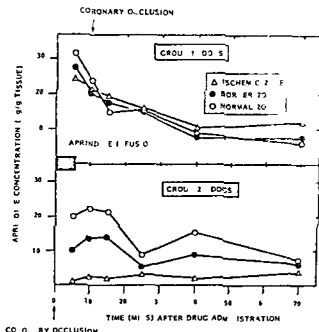

Fig 5 Regional myocardial aprindine concentrations among dogs of group 1 (given aprindine prior to coronary artery occlusion) and group 2 (aprindine after coronary artery occlusion) as a function of time after the onset of aprindine infusion Among group 2 dogs the differences between ischemic border and normal zone aprindine concentrations were all significant ($P<0.01$)

ing that verapamil has little or no effect on the rapid sodium and potassium transcellular fluxes

Clinical applications

Intravenous verapamil has several important clinical applications and may be used for the following conditions (1) the treatment of coronary artery spasm (2) the treatment of hypertensive crises and (3) the treatment of supraventricular tachyarrhythmias It has also been used for such noncardiac conditions as relaxation of the uterus in threatened abortion and premature labor[2]

Treatment of coronary artery spasm There are many causes of ischemic heart disease A mechanism that has received increasing emphasis and recognition during recent years is coronary artery spasm The recognition of this mechanism has in part been due to the increasing sophistication of available techniques for demonstrating such spasm Thus coronary artery spasm is being increasingly recognized as a cause of the variant form of angina pectoris—Prinzmetal s angina [5] and its potential role in the enigma of sudden death has become especially important[6] It is interesting to note that Heberden postulated the mechanism of coronary artery spasm as early as 1768 and such medical giants as Osler[8] and Gallavardin echoed this in later years Clearly then, the advent of an important coronary spasmolytic agent is thus particularly important and especially so in the present day coronary milieu where palliative surgical coronary artery bypass is becoming an all too frequent event

The frequency of coronary artery spasm has recently received special emphasis through the elegant studies of Maseri et al by means of continuous ECG and hemodynamic monitoring they documented 8 000 to 9 000 episodes of transient acute myocardial ischemia These were reflected by S T-segment elevation or depression and T wave changes The ECG changes occurred within minutes of the onset of pain but could also occur in the absence of pain They also showed that spasm could occur in apparently normal coronary arteries and lead to S T-segment elevation to be followed shortly thereafter by deeply inverted T waves During the phase of T wave inversion these patients usually developed ventricular tachycardia which sometimes progressed to ventricular fibrillation and sudden death The only way these episodes of ventricular fibrillation could be prevented was by treating the symptom i e the relief of the vasospastic angina pectoris and not by the administration of antiarrhythmic drugs They conclude that preventing angina meant preventing ventricular fibrillation in these cases This observation is of particular significance since it heralds an entirely new therapeutic approach And in this respect verapamil is highly effective by both the oral route[9] and the intravenous route[11] in abolishing ameliorating and preventing coronary vasospastic attacks as reflected by angina of effort angina at rest and in particular Prinzmetal s angina

Treatment of hypertensive crises Hypertensive crises respond dramatically to the administration of intravenous verapamil[1 1] Blood pressure control is usually achieved within 1 to 2 minutes following the intravenous injection of 5 mg of verapamil The effect is due to a reduction in peripheral vascular resistance and is in no way related to any negative inotropic effect In this respect it is important to note that intravenous verapamil does not reduce normal blood pressure or at most has only a negligible and unimportant effect

Treatment of supraventricular tachyarrhythmias Intravenous verapamil was first used for the treatment of arrhythmias in the late 1960s and my experience with this agent both on an investigational basis and in routine clinical practice now involves many hundreds of cases and extends over a decade Most of these patients had grade IV cardiac failure and received digitalis therapy This experience has left me with no doubt whatsoever that verapamil is the best available pharmacologic agent for rapid action in affecting A V nodal delay or block This property is of particular value in interrupting the conduction circuit of a reciprocating tachycardia and thereby terminating the attack Note that it makes no difference which anatomic bypass is used in the reciprocal circuit—a James bypass an intranodal pathway a Kent bundle or a Mahaim fiber—since termination is effected by block within the A V nodal part of the circuit and not within the bypass

The Investigators Brochure of the Knoll Pharmaceutical Company reflects a review of 134 studies involving the use of intravenous verapa

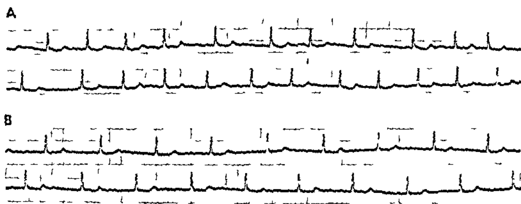

Fig 1 A Section of the control tracing (continuous strip of standard lead II) showing atrial fibrillation with irregular ventricular response B Tracing recorded after the administration of intravenous verapamil shows regularization of the ventricular response

mil for the treatment of various arrhythmias There were 4 379 documented arrhythmic episodes treated with intravenous verapamil some of which are considered in further detail below

Supraventricular tachycardia The Knoll review reflects 1 607 published episodes of supraventricular tachycardia treated with intravenous verapamil Of these 1 307 (81%) were converted to normal sinus rhythm and 139 (9%) reflected a significant reduction in rate The precise mechanism of the supraventricular tachycardia however was not always certain and no distinction in this analysis could therefore be made between ectopic atrial supraventricular tachycardia and reciprocating tachycardia Such distinction however is very important in the evaluation of this drug Thus my experience comprises 59 cases of the reciprocating form of supraventricular tachycardia Eighteen of these cases involved retrograde conduction through a Kent bundle one was associated with anterograde conduction through a Kent bundle and two were associated with retrograde conduction through a Mahaim fiber The precise anatomic substrate for the circus movement could not be determined in the remaining 38 cases although the diagnosis of reciprocating tachycardia was clear The reciprocal circuit could have involved an intranodal bypass a James bypass or retrograde conduction through a Kent bundle or Mahaim fiber The reciprocating tachycardia was terminated with conversion to normal sinus rhythm in all 59 cases (100%)

Atrial flutter The Knoll review reflects 343 documented episodes of atrial flutter treated with intravenous verapamil Of these 31% were converted to normal sinus rhythm and a significant reduction of the ventricular response was obtained in 186 (54%) My experience comprises 87 patients with atrial flutter all of whom had a reduction in ventricular response Thirteen (15%) of these subsequently converted to normal sinus rhythm Eleven (13%) converted to atrial fibrillation two of which subsequently converted to normal sinus rhythm

Atrial fibrillation The Knoll analysis reflects a total of 1 474 documented episodes of atrial fibrillation treated with intravenous verapamil Of these 230 (16%) were converted to normal sinus rhythm and a significant rate reduction was obtained in 1 149 (78%) The data include my own investigational experience of 115 cases[7, 17] Of these 115 cases, a reduction in ventricular response was obtained in 111 (97%) The higher the initial control rate the higher the ensuing reduction following the administration of intravenous verapamil There was also a diminution in the amplitude of the fibrillating deflections in 44% of cases In contrast to other studies in which conversion to sinus rhythm was obtained in a moderate number of cases there was no conversion to sinus rhythm in the studies of Schamroth et al[6, 7] A possible reason for this was the advanced state of disease and the marked associated cardiomegaly in most of these patients

A noteworthy feature was an associated regularization of the ventricular response in most of these patients This occurred in the presence of continuing atrial fibrillation and in the absence of complete A V block[6] (Figs 1 and 2)

Amiodarone in the treatment of cardiac arrhythmias in children One hundred thirty five cases

Philippe Coumel M D and Jean Fidelle M D *Paris and Les Loges en-Josas France*

Oral amiodarone was g ven to 135 children (mean age 10 2 years) for a mean duration of 4 1 months (range 1 day to 6 years) for mainly id opathic (25 /) and postoperative (61 ʹ) arrhythm as Complete ECG control or partial ECG control with cl nical improvement was obtained in 60 / and 33% of cases respectively regardless of the arrhythmia location (atrial 69% junctional 16% and ventricular 15 /) mechanism resistance (55 /) or sensitivity (45 %) to other drugs and presence of card omegaly (40) or clin cal signs of heart failure (27 /) The only factor favoring improvement was a short history (< 2 months in 54 %) The rapid onset of drug effect (4 1 days) the early relapses after treatment discontinuation (3 3 weeks) and the absence of side effects due to drug accumulation reflect a faster metabolism than that in adults with no cardiac tox city and a low incidence of thyro d dysfunct on (2 hyperthyroid 1 hypothyroid)

Two factors are responsible for the greater difficulty in treating arrhythmias in children compared to adults (1) the many different types of arrhythmias some of which are refractory and peculiar to children and (2) the limitations of therapeutic choice due to greater drug toxicity This is why amiodarone is a considerable therapeutic asset in children We report here our experience since 1971

Material and methods

The study includes 135 children (80 boys and 55 girls) ages 0 to 15 years (Fig 1) treated and followed up from 1971 to 1979 and also includes a previously published study[1] of 50 patients The diagnosis and cause of the arrhythmias are detailed in Tables I and II The predominance of atrial (69%) and postoperative arrhythmias (61%) is emphasized as well as some resistant arrhythmias such as permanent reciprocal tachycardia[2] congenital ectopic His bundle tachycardia[3] (Figs 2A and 2B) and catecholamine ventricular tachycardias (Fig 3)

The arrhythmias were accompanied by clinical cardiac failure in 27% isolated radiologic cardiomegaly in 40% and were well tolerated hemodynamically in only 33% of the cases The arrhythmias were chronic (lasting more than 2 months) in almost half of the cases (46%) In over half (55%) the arrhythmias were resistant to the various antiarrhythmic drugs used in children i.e digitalis disopyramide beta blockers atropine and verapamil Among the remaining patients some had no treatment other than amiodarone because they had well known resistant arrhythmias

The initial treatment was a daily oral dose of 800 mg of amiodarone adjusted according to the child s surface area This dose was maintained for an average of 2 weeks then reduced by half and was finally given 5 days out of 7 Because of our adult experience and the large predominance of supraventricular arrhythmias most of the patients were also digitalized Digitalization was always achieved before amiodarone was given in cases of cardiac failure and was associated with a diuretic In a small number of cases (eight patients) one single dose of amiodarone was given

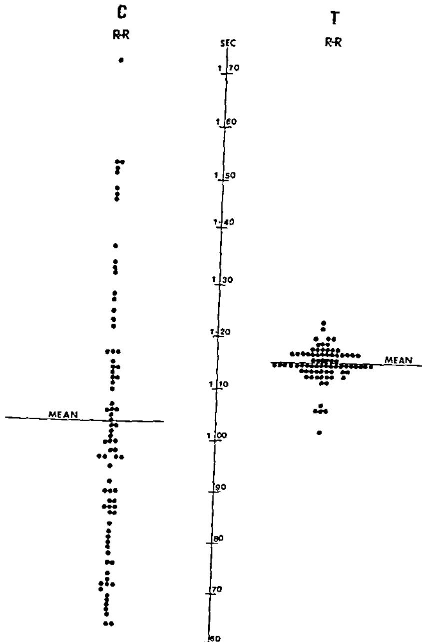

Fig 2 ~ win, the "regularization of the ventricular rhythm C = scatter of the R R intervals in the contr ig atter of the R R intervals in the second test tracing

The mechani m of the egularizing effect is uncertain It is unlikely to b due to the development of complete A bl ck with A V nodal escape rhythm since th e ape rhythm is too fast and some irregularity i till present It may result from a stabilizing effect on the varying degrees of concealed A V nodal conduction which may cause the irregular ventricular response in atrial fibrillation—perhaps by increasing the absolute but not relative refractory period An activation front approaching the atrioventricular node from the direction of the SA node is well transmitted whereas a front approaching from other directions may be delayed or blocked Verapamil may stabilize the chaotic atrial activation front

Results

The results were considered go[illegible] sinus rhythm was reestablished a[illegible] cardiac rate was reduced but the [illegible] not perfectly controlled on the [illegible] when the treatment clinically an[illegible]

This regularization effect has recently also been noted following the administration of large doses of oral verapamil[1]

Ventricular tachycardia The Knoll analysis reflects a total of 239 documented episodes of ventricular tachycardia treated with intravenous verapamil Of these 239 episodes 157 (66%) were apparently converted to normal sinus rhythm This contrasts with my own experience in which no effect was noted in ten cases of extrasystolic ventricular tachycardia and I have stopped using verapamil for this purpose This difference in experience may be due to the fact that here again the precise mechanism of the ventricular tachycardia was delineated Thus for example an idioventricular tachycardia will be abolished if its rate is slowed relative to the sinus rate Extrasystolic ventricular tachycardia will not be affected in this way

Contraindications

Verapamil is a safe drug provided certain basic contraindications are heeded The drug should not be administered under the following circum stances cardiogenic shock any degree of A V block structural nodal disease (the so called sick sinus syndrome) hypotension (except where due to a tachyarrhythmia as such) and in association with beta blocking agents or disopyramide

Comments Verapamil should also be used with caution in the presence of intraventricular con duction defects

The so called sick sinus syndrome is an unfor tunate term for it is abundantly clear that it is not only the sinus node which is so to speak sick but also the A V node and its appendages Struc tural nodal disease is preferred since it connotes a widespread disease process involving the con ducting system Verapamil is contraindicated when any manifestation of this syndrome is evi dent

The negative inotropic effect Verapamil has a slight negative inotropic effect which is usually insignificant This is more than counterbalanced by the reduction in the peripheral resistance and the reduction in cardiac work resulting from the diminution in the afterload as indicated by Fer linz et al

The question of adverse side effects

I have had no deaths or adverse effects in any of my patients Four deaths following the adminis tration of verapamil have been reported in the world literature The circumstances in all these cases however were either bizarre and/or clear contraindications were present Thus (1) The case reported by Sacks and Kennelly[1] was that of a 63 year old man in *cardiogenic shock* and who also had *bifascicular block* one (2) The case reported by Witchitz et al was a 63 year-old woman with *sarcoma of the heart* (3) The case reported by Apitz and Gaismarer[3] was that of a 10 year old boy with *fibroelastosis* who had *first to third degree A V block* (4) The case reported by Heck et al[4] was that of a 57 year old man who was seriously ill with myocardial infarction and in whom *digitalis and verapamil* were administered intravenously *within a few minutes of each other*

Conclusions

Verapamil the pioneer of calcium ion antagon ists represents an important milestone in clinical therapy Its present status in cardiologic practice is that of significant benefit in three important conditions

It stabilizes and slows or blocks conduction in the A V node and is the drug of choice for action on this structure It has an important coronary spasmolytic action where its full potential has not as yet been realized Its reduction of periph eral vascular resistance is important in the treat ment of hypertension And intravenous adminis tration is of particular value in dealing with crises related to these situations The reduction in cardiac afterload also has a beneficial effect on the ailing heart

The future will see expansion of clinical appli cation to other clinical disciplines where smooth muscle relaxation is the therapeutic aim Verap amil thus heralds an exciting new era a new dimension in therapeutic approach

I wish to thank the Photographic Unit Department of Medicine University of the Witwatersrand for the photo graphic reproductions.

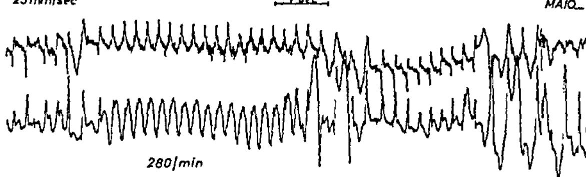

Fig 3 Catecholamine related severe ventricular tachycardia in an 8 year old boy A strip from the Holter monitoring clearly shows the mechanism of the Adams Stokes syndrome very rapid and polymorphic attacks of ventricular tachycardia and fibrillation are readily induced by exercise Beta blockers were only partially effective and a new 6-year treatment with amiodarone did control the arrhythmia

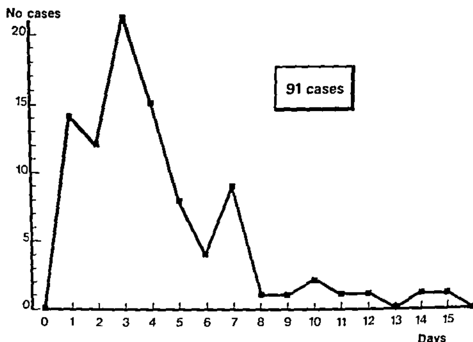

Fig 4 Delay before response to amiodarone treatment In 91 patients in whom the delay could be precisely evaluated the great majority (83) responded during the first week of treatment (one fourth at the third day) This is in contrast to the necessary 7 to 10 day impregnation in adults

graphically was ineffective The results were good in 81 cases (60%) average in 44 (33%) and poor in only 10 (7%) i e more than 90% of the cases totally or partially improved The cause of the arrhythmia its mechanism (ectopic focus or reentry) localization (Table III) and resistance to other antiarrhythmics (Table IV) do not affect drug efficacy (Pearson chi square test) although a longer duration of the arrhythmia (greater than 2 months) resulted in less drug effectiveness ($P < 0\ 10$)

The delay before response to treatment coul be evaluated in 91 patients and is represented i Fig 4 It ranges from 1 to 16 days and its mea value is 4 1 days with a peak at day 3 In eigh cases of supraventricular tachycardia a full sin gle dose of oral amiodarone was given and rhythm reduction was obtained between 5 and 7 hours i seven patients and after 24 hours in one

Conversely the delay before relapses afte interruption of treatment could be assessed in 3 cases of serious chronic and recurring arrhyth

Hemodynamic and electrophysiologic interactions between antiarrhythmic drugs and beta blockers, with special reference to tocainide

Hamid Ikram M D *Christchurch New Zealand*

The administration of beta receptor blocking drugs and antiarrhythmic drugs in close proximity may result in hemodynamic electrophysiologic or pharmacokinetic interactions We examined the hemodynamic and electrophysiologic effects of 0 20 mg/kg intravenous metoprolol followed by a 15 minute infusion of 0 75 mg/kg/min tocainide In the six patients studied metoprolol produced a fall in cardiac rate and output which was not further altered by tocainide Both drugs decreased peak left ventricular (LV) dP/dt ejection fraction and mean V_{cf} There was no change in LV end-diastolic pressure or echo dimension and in clinical ill effects In eight patients without sinus or A V nodal disease electrophysiologic studies showed mild depression of A V conduction by metoprolol Tocainide depressed s nus node function and shortened the functional refractory period of the His Purkinje system There were no cl nical sequelae However three patients with preexisting electrophysiologic abnormalities developed asystole There was no evidence of pharmacokinetic interaction It is concluded that metoprolol and tocainide can be given concurrently with reasonable safety to cardiac patients without electrophysiologic abnormalities

Antiarrhythmic drugs are frequently given con currently with beta adrenoreceptor drugs pre scribed for angina hypertension or arrhythmias Such combinations may result in serious adverse effects from drug interactions These are of three types

First there is hemodynamic interaction This was exemplified by the development of circula tory collapse after intravenous verapamil had been given to a patient already on propranolol[1] Another patient in this series with Wolff Parkin son White syndrome developed cardiogenic shock when propranolol was added to the vera pamil therapy which was already being adminis tered Seabra Gomes et al showed that when intravenous practolol and verapamil were given individually to patients whose heart rates had been fixed with atrial pacing there was little hemodynamic alteration However the adminis

tration of the two drugs together resulted in pronounced fall in cardiac output They advis caution in the combined use of these drugs patients with impaired myocardial function

Second drug interactions may depress elect cal activity Asystole has been reported in t patients on beta blockers who were given intr venous verapamil[1] Both of these patients h normal A V conduction Patients with impair A V conduction or the sick sinus syndrom should be treated with great caution with comb nations of verapamil and beta blockers

Serious electrophysiologic side effects ha been reported with combinations of disopyram and beta blocking drugs Gelipter and Ha e reported severe bradycardia and no effective ca diac output in a 56 year old man with myocardi infarction who was being treated with disopyram ide and who had previously been given pract lol

Cumming and Robertson reported two cases supraventricular tachycardia in which seve hypotension and bradycardia occurred wh practolol and disopyramide were used togeth

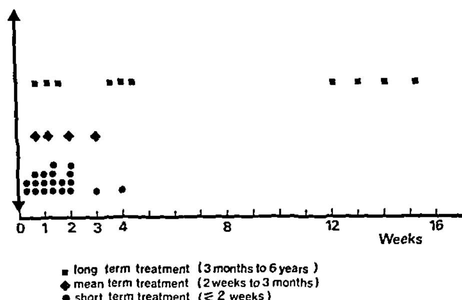

Fig 5 Delay before relapse of chronic arrhythmias after cessation of treatment In 34 patients in whom the recurrence of the arrhythmia could be evaluated it occurred within 2 weeks in 24 after 3 to 4 weeks in six and after 12 to 16 weeks in four

mias (Fig 5) Its mean value was 3 3 weeks and in 24 cases it was 2 weeks or less The duration of treatment and child s age affect the delay before relapse In 10 treatments lasting between 3 months and 6 years relapses occurred three times in 2 weeks three times in 4 weeks and four times in 2 to 3 months

Concerning children and long term treatments particular attention must be paid to drug tolerance Electrocardiographically repolarization changes must occur before a treatment failure is accepted i e before the appearance of increased height of U waves and lengthening of the Q T segment The sinus rate was steadily reduced but in only 10 cases was it less than 60/min at rest and in seven of these patients there was a preexisting atrial rhythm disturbance The three cases of sinoatrial block were preexisting We observed no intra atrial conduction disturbances The P R lengthening was from 40 to 80 msec in 41 cases with Wenckebach periods in three cases We observed no distal A V conduction disturbance in spite of 52 cases of complete right bundle branch block 15 of which were associated with a left anterior hemiblock The QRS duration increased by 20 to 40 msec in two cases of incomplete right bundle branch block

Corneal deposition (three cases) photosensitivity (four cases) and bluish skin coloring (one case after 72 months of treatment) were rarely observed and only in older children In four cases

One of these patients died The other developed a further episode of supraventricular tachycardia which was treated without untoward effect by disopyramide alone This suggests that it is the combination rather than the individual drug that leads to problems The combined use of beta blockers and disopyramide is relatively contraindicated.

Amiodarone a new antiarrhythmic drug has also been reported to cause asystole and severe bradycardia when given in close proximity to propranolol Asystole and depression of myocardial contractility have also been reported with propranolol therapy for digitalis toxicity This complication is frequent enough to preclude beta blocker treatment for digitalis toxicity unless everthing else has failed

A third type of interaction is where one drug interferes with the pharmacokinetics of another Administration of propranolol reduces the clearance of lidocaine and quinidine

We studied the hemodynamic electrophysiologic and pharmacokinetic effects of tocainide in patients who were given intravenous metoprolol shortly before tocainide

Material and methods

Hemodynamic interactions of tocainide Hemodynamic observations were made on six patients five men and one woman undergoing routine diagnostic catheter studies A Swan Ganz catheter was positioned in the pulmonary artery for measurement of pressure and thermal dilution cardiac output The left ventricular pressure was measured by means of a Millar catheter tip manometer Left ventricular dimensions were recorded simultaneously by M mode echocardiography Following control measurements metoprolol was infused in a dose of 0 20 mg/kg over a 5 minute period Hemodynamic and echo measurements were recorded at the end of the infusion and 15 minutes later Tocainide was then infused in a dose of 0 75 mg/kg/min over a 15 minute period Hemodynamic measurements

2 60 gm/L) In these three patients the thyroid dysfunction (two hyperthyroid one hypothyroid) completely regressed in several weeks with cessation of treatment Biologic surveillance confirms the rarity of thyroid complications in the present experience plasma cholesterol levels Hamolsky test T_3 T and TSH were monitored before and after a mean duration of 14 5 months of treatment in 40 patients No variation exceeding the normal range for these tests was observed except in the three previously mentioned patients

Discussion

After amiodarone has been used for more than 10 years as an antiarrhythmic in adults, it is not necessary to emphasize its effectiveness and uniqueness However its overall effectiveness does not replace other antiarrhythmics and moreover its problems of tolerance or thyroid toxicity should not make it an initial simple therapeutic approach These side effects were carefully considered before this drug was used in children and only its extraordinary effectiveness and the observed excellent tolerance encouraged us to increase its use over the 9 year period We know of only one equivalent experience (Kreutzer BA Personal communication)

Amiodarone cured or improved arrhythmias in six out of ten patients and improved their tolerance in three out of four remaining patients whatever the mechanism localization and previous resistance This is without evidence of poor tolerance or nonreversible toxicity and represents almost all the desirable properties for an ideal antiarrhythmic It is mostly on a matter of principle that one should not use this as the first medication in childrens rhythm disturbances even though it is more consistently effective and better tolerated than in adults

The drug is metabolized more rapidly in children with the onset of action in 4 days instead of 10 days as in adults and effectiveness after cessation lasts less than a few weeks as opposed to several months in adults These are the norms found in animal experiments from which we also know that the drug concentration in the adipose tissue and muscle is 10 to 30 times greater than in the plasma There is no plasma assay to regulate the dosage used in a clinical setting and in any case the tissue binding might invalidate normal pharmacokinetic parameters and should not be interpreted as rigorously as for other drugs The fact that children have less adipose tissue than adults may account for the faster metabolism in the former but probably this is not the only difference and does not explain the unique phenomenon of corneal deposits in adults The drug s primary and secondary effects obviously vary with age and this is clearly visible in the older child who tends to react as an adult

It is in this regard that the younger the child and the more recent the arrhythmia the more oral amiodarone is likely to be an effective emergency treatment able in a few hours to terminate a reciprocal junctional paroxysmal tachycardia or an atrial or ventricular tachycardia while avoiding the dangers of other antiarrhythmics The mechanism of action of amiodarone is clearly known and it reduces the outward potassium current as well as the rapid inward sodium current without being classed as a membrane stabilizing agent Also it is not a beta blocker but nevertheless slows the beta response[6] Finally it has no effect on the slow calcium canal and its essential action is to lengthen the duration of the action potential and refractory period A single mechanism of action seems to fit poorly with the drug s widespread effectiveness in a great many different arrhythmias It is rare to combine amiodarone with other antiarrhythmics with the exception of digitalis whose supraventricular antiarrhythmic action is synergic In addition digitalis alone can compensate for amiodarone s real although moderate depressive myocardial effect[7]

The demonstration of wide clinical efficacy does not dictate indications for medication However one can recognize cases in which one should directly resort to this treatment In practice this applies to all poorly tolerated arrhythmias, as it is the least dangerous in the presence of poor myocardium In the long run it does not necessarily have to be maintained except in special resistant life or death childhood arrhythmias as such certain long term atrial tachycardias, chronic reciprocal tachycardias ectopic focus tachycardias in infants and catecholergic ventricular tachycardias when not controlled by beta blocking treatment

Therapeutic ranges (1) Tocainide 18 to 80 μmol/L, and ( ) metoprolol 0.2 to [illegible]0 μmol/L (no exact therapeutic range levels are approximately those produced by 100 mg b.i.d. dose)

done once after metoprolol and twice after tocainide

Results

Hemodynamic interactions The hemodynamic findings are summarized in Table I There was a significant fall in heart rate and cardiac output following metoprolol but no additional fall after tocainide Left ventricular dP/dt max fell significantly after beta blockade and there was a further fall after tocainide Left ventricular end diastolic pressure was not altered significantly although pulmonary wedge pressure rose after tocainide but not after metoprolol Echo end diastolic dimensions were not altered after either drug There was a significant fall in mean V[illegible] and ejection fraction 15 minutes after metoprolol and again 15 minutes after tocainide

Electrophysiologic interactions The electrophysiologic results are detailed in Table II There was no change in resting heart rate The A H interval increased significantly after metoprolol but was not further affected by tocainide The H V interval was unchanged The corrected sinus node recovery time was not significantly altered during the study except that at pacing rates over 100/min there was a significant lengthening following tocainide administration The atrial pacing rate required to induce A V Wenckebach effect was significantly decreased by metoprolol but was not further altered by tocainide The refractory periods both functional and effective of the atrium A V node and right ventricle showed no significant change There was however a significant shortening of the His Purkinje system There was no consistent action on ventriculoatrial conduction (Table II)

Discussion

In our study metoprolol and tocainide singly and in combination appeared to have little influence on electrophysiologic parameters in patients who were free from sinus node disease or impaired A V conduction However when this protocol was administered to patients with underlying electrophysiologic abnormalities there was serious depression of sinus node function and A V conduction

The plasma levels of both drugs remained in the therapeutic range (Table III) There was no obvious evidence of pharmacokinetic interaction although this was not a formal pharmacokinetic study The plasma levels of both drugs immediately after infusion in the hemodynamic study were much higher than those in the electrophysiologic study This probably reflects a difference in sampling technique in that samples for the hemodynamic studies were taken from the right atrium while those for the electrophysiologic study were taken from a peripheral vein in the left arm

In conclusion the administration of tocainide and metoprolol to patients with heart disease results in a small depression of myocardial contractility This does not result in clinical sequelae Administration of the drugs especially metoprolol results in a mild depression of A V nodal conduction Tocainide shortens the functional

The clinical use of intravenous verapamil

Leo Schamroth M D *Johannesburg South Africa*

The mechanisms of action and clinical application of verapamil—a calcium ion antagonist—are reviewed Verapamil is effective and has important application in the treatment of coronary artery spasm hypertensive crises and supraventricular tachyarrhythmias

Present day pharmacologic practice usually takes the form of what might well be termed variations on a theme There are for example many variations on the penicillin theme numerous permutations on the phenothiazine theme and a thematic multiplicity of beta blocking agents Only rarely is there an event that truly constitutes a major pharmacologic breakthrough a breakthrough that reflects the development of an entirely new pharmacologic principle with dramatic clinical effects and exciting potential The introduction of calcium ion antagonists heralded by verapamil constituted such an event An event moreover that was no novel in pharmacologic action that it necessitated the addition of a fourth class to the original three class classification of antiarrhythmic substances by Singh and Vaughan Williams This new class of drugs not only inhibits the transmembrane transport of calcium ions but affects the relationship between excitation contraction coupling with profound effects on smooth muscle particularly vascular smooth muscle and on myocardial inotropism effects which have important application to clinical and especially cardiologic therapy

Basic pharmacologic action

Verapamil has three basic pharmacologic effects (1) it restricts the conversion of ATP to ADP (2) it delays or blocks conduction within the A V node and (3) it diminishes vascular and other smooth muscle tone

From th Un v rsity of th Witwatersrand nd B r gw nath Hosp tal Johannesbu g S th Africa

Repr req est Leo S hamroth M [illegible] of Med cine and Chief [illegible] Uni ers ty of W [illegible] P O Bo 2013 Johannesburg S uth Afri a

Restriction in the conversion of ATP to ADP Verapamil blocks or restricts the conversion of ATP to ADP and the consequent release of a high energy phosphate bond This results in a reduction of high energy phosphate consumption which in turn leads to a reduction in contractile tension The oxygen requirements of cardiac muscle are thereby decreased

Delay or block of conduction within the A V node A V nodal delay or block has two major therapeutic implications (1) Supraventricular impulses of atrial tachycardia atrial flutter or atrial fibrillation will be subject to increasing A V block This will reduce the ventricular response with a consequent reduction of ventricular rate (2) The circus movement of a reciprocatin supraventricular tachycardia will be interrupted within the A V node and the tachycardia thereby terminated

Diminution of vascular tone Diminution of vascular tone results in (1) coronary dilatation which thereby improves myocardial oxygen supply and (2) peripheral vasodilatation which results in a reduction in peripheral resistance with a consequent reduction in blood pressure Furthermore the reduction in peripheral resistance will also reduce the cardiac afterload and thereby the workload of the heart

Electrophysiologic effect

The plateau phase—phase 2—of the cardiac action potential is due at least in part, to a slow inward flow of calcium ions into the cell Verapamil blocks or retards this slow inward flow of calcium ions and thereby slows or prolongs both phases 2 and 3 of the cardiac action potential It has no effect on the other phases thereby indicat

refractory period of the His Purkinje system Apart from this there is little effect on conventional electrophysiologic indices in patients who are free from sinus atrial or A V nodal disease Thus they can be used with reasonable safety in these patients However, in patients with the sick sinus syndrome and impaired A V conduction significant depression of function occurs Hence their combined use in these situations is to be avoided

documented ventricular tachycardia or ventricular fibrillation 43 (74%) also had repetitive ventricular responses due to *intraventricular reentry* following ventricular stimulation The *intraventricular* reentrant complexes in these patients were morphologically similar to *their* spontaneous or subsequently induced tachyarrhythmias (Fig 2) Twenty five (58%) of these 43 patients manifested isolated *intraventricular* reentry while the remaining 18 demonstrated both intraventricular reentry and bundle branch reentry However intraventricular reentry occurred in *only 9 1% (31 of 342)* of patients without malignant ventricular arrhythmias ($p < 0.001$) None

Shortcomings of the Lown grading system for observational or experimental studies in ischemic heart disease

J Thomas Bigger Jr M D and Francis M Weld M D
New York N Y

The Lown grading system uses three levels of frequency and four complex features to grade ventricular arrhythmias The seven Lown grades are mutually exclusive (a patient can be in only one grade) and hierarchical (higher grades indicate increased likelihood of death) *We evaluated the ability of the Lown arrhythmia grading system to predict death in 400 patients who were convalescing from acute myocardial infarction* Lown grading produced a poor distribution among grades of the population lacked a monotonic increase in risk with increasing arrhythmia grade lacked a substantial risk gradient between grades and showed a lack of isometry in the higher grades Also the Lown grading system thwarts the use of standard multivariate techniques for relating the frequency and characteristics of ventricular *premature depolarizations (VPDs) to cardiac death We also examined the utility of the Lown arrhythmia* equation for evaluating the results of antiarrhythmic drug therapy The Lown grading system failed to reveal clearly the change in VPD frequency and characteristics as a function of drug dose *We propose an* alternative grading system that is not mutually exclusive or hierarchical This grading system lacks many of the flaws of the Lown grading system and is suitable for standard multivariate analyses but like the *Lown grading system still fails to show the relationships among ventricular arrhythmias time drug* dose and activity

In 1971 Lown and Wolf[1] proposed a grading system for ventricular arrhythmias They contended that ventricular arrhythmias are so common in ischemic heart disease that their mere presence has little significance However these authors argued further that certain characteristics of ventricular premature depolarization (VPD) do identify persons who are prone to sudden cardiac death these characteristics are high frequency multiform VPDs repetitive VPDs and early cycle VPDs Using these VPD features they devised a system to grade ventricular arrhythmias in terms of prognostic significance The VPD grades were arranged in ascending order of gravity i e likelihood of dying In 1975 the Lown arrhythmia equation" was introduced primarily for use in experimental studies In this article we will discuss the shortcomings of the Lown system for grading ventricular arrhythmias in observational studies and in experimental studies with antiarrhythmic drugs

Use of Lown grading system in observational studies

The Lown grading system has been used to study the associations between ventricular arrhythmias and other variables or outcomes e g sudden cardiac death For example the Lown grading system has been used to investigate the relationship between ventricular arrhythmias and coronary anatomy or left ventricular dysfunction In this section we will evaluate the utility of the Lown grading system for predicting *outcome in patients who survive acute myocardial infarction* For this purpose we will use a group of 400 patients that we studied during their admission for acute myocardial infarction Each patient had a 24 hour ECG recording made 10 to 24 days after infarction These 24 hour ECG tapes were analyzed for ventricular arrhythmias by the digital computer program Columbia IV

The automatic implantable defibrillator

M Mirowski M D Morton M Mower M D and
Philip R Reid M D *Baltimore Md*

The automatic implantable defibrillator is an electronic device programmed to monitor the cardiac rhythm continuously to recognize ventricular fibrillation and ventricular tachyarrhythmias characterized by sinusoidal waveform and to deliver corrective defibrillatory discharges when indicated Three patients suffering from recurrent malignant ventricular arrhythmias refractory to medical therapy underwent permanent implantation of this device Seven episodes of ventricular tachycardia and flutter fibrillation were documented during the weeks following the implantations two were induced at electrophysiologic studies and five occurred spontaneously All were correctly identified and six were automatically reverted to normal sinus rhythm by the implanted device one induced episode was cardioverted externally before the unit could recycle Although many problems remain to be solved and the ultimate value of this therapeutic modality has to be determined a new approach to prevention of sudden death in patients at high risk of developing lethal ventricular arrhythmias has become available

The continuing inability to deal effectively with malignant ventricular arrhythmias outside the hospital setting has prompted the development of a clinically applicable automatic implantable defibrillator[1] This device is programmed to monitor the cardiac rhythm continuously to recognize ventricular fibrillation and ventricular tachyarrhythmias characterized by sinusoidal waveforms[2] and to deliver corrective defibrillatory discharges when indicated The chief objective of the automatic defibrillator is to protect patients at particularly high risk of sudden death whenever and wherever they are stricken by these lethal arrhythmias [5] In comparison to services provided by a coronary care unit, the implanted device has the unique advantage of being permanently available to the patient at risk without interaction of specialized personnel or the need for additional equipment Conceptually the implantable defibrillator is analogous to an implantable demand pacemaker except that malignant ventricular arrhythmias instead of asystole are sensed and the delivered pulse has appropriate defibrillating characteristics

Description of the device

The first clinical model of the automatic implantable defibrillator (Fig 1) is encased in titanium and hermetically sealed with a laser weld It weighs 250 gm and occupies a volume of 145 cc All materials in contact with body tissue are biocompatible The defibrillating electrodes are made from titanium and silicone rubber One electrode designed for placement in the superior vena cava near the right atrial junction is located on the distal end of an intravascular catheter The second electrode in the form of either a cup or a flexible rectangular patch is placed extrapericardially over the apex of the heart The outside surface of the apical electrode is insulated to achieve optimal current distribution

The device is powered by lithium batteries having a projected monitoring life of approximately 3 years or a discharge capability of approximately 100 shocks The sensing system detects ventricular fibrillation by monitoring a sampled probability density function of the ven

Table II Comparison of three VPD frequency criteria for risk stratification in 400 patients after acute myocardial infarction

Data	*VPD frequency*		
	≥ 1/hr	*≥ 10/hr*	*≥ 30/hr*
No of patients	190	99	56
No of deaths	57	37	24
Chi square	23 1	23 4	1 5
Odds ratio	3 [illegible]	3 6	3 6
Sensitivity (%)	73	47	30
Specificity (%)	59	81	89
False positive rate (%)	71	64	60
False negative rate (%)	10	14	16

Major characteristics of the Lown grading system The Lown grading system uses three levels of frequency and four complex features to grade ventricular arrhythmias (Table I) The grades are mutually exclusive and hierarchical The system is mutually exclusive in the sense that a person can only be in one grade The system is hierarchical in two senses (1) the grade depends on the rank of the VPD features and (2) higher grades imply higher risk Each grade is assumed to have a poorer prognosis than those lower in the hierarchy

Frequency Since 1971 0 and 30 VPDs/hour have been used to partition patients into grade 0 1 or 2 It seems reasonable to select 0 VPD/hour as one of the stratifying criteria However the rationale for 30 VPDs/hour is less clear In our 400 postinfarction patients 1 0 VPD/hour is at the fiftieth percentile and 10 VPDs hour is at the seventy fifth percentile The Lown criterion for high frequency is at the eighty seventh percentile i.e only 13% of our 400 patients had 30 or more VPDs/hour Table II compares the frequency criteria of ≥ 1/hour ≥ 10 hour and ≥ 30 hour for death sensitivity specificity etc When choosing the partition value for VPD frequency the physician must consider the action to be taken in the high or low risk stratum If the low risk group is to receive treatment and follow up at a reduced level of intensity the criterion of 1/hour is best Conversely if the high risk group is to receive treatment that produces very significant undesirable effects, 30/hour is the best criterion because only about 15% of the population would be exposed to the adverse effects of treatment For many treatments the 10/hour criterion may be the best compromise between sensitivity and specificity It selects the 25% with the highest mortality rate for treatment and thus fails to expose the other 75% to the risks of treatment

It is important to remember that in the Lown grading system patients who have complex features are not classified according to VPD frequency [8] For example only 85 (30%) of the 280 patients who had a VPD frequency greater than 0/hour but less than 30/hour remained in grade 1 Similarly only 2 (4%) of the 56 patients with 30 or

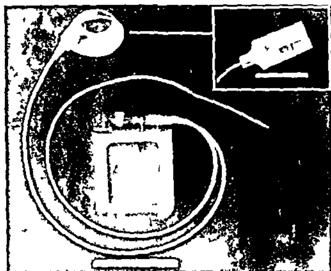

Fig 1 Automatic implantable defibrillator with its two defibrillating electrodes The insert in the upper right corner shows a patch electrode used as an alternative to the apical cup electrode

tricular electrical activity This function defines the fraction of time spent by the differentiated input electrogram between two amplitude limits located near zero potential For all practical purposes ventricular fibrillation is identified by the striking absence of isoelectric segments The device will also respond to ventricular flutter or ventricular tachycardia characterized by sinusoidal waveform if the probability density function criteria are satisfied Borderline rate and waveform characteristics of some arrhythmias may result in a delay in detection and thus in the pulse delivery The important advantages of this method of detection are its reliability low standby power requirements and most important a passive mode of failure Such a failure mode tends to ensure that possible sensing or mechanical faults will not be interpreted by the device as fibrillation and thus will not result in spurious shocks

When a suitable ventricular arrhythmia is detected the device delivers a truncated exponential pulse of 25 J 15 to 20 seconds after onset of the arrhythmia the pulse duration ranges between 3 and 8 msec as a function of the interelectrode resistance The device can recycle three times if previous discharges are ineffective, with the strength of the third and fourth pulses increased to 30 J After the fourth discharge about 35 seconds of nonfibrillating rhythm is required to reset the counter and to allow a full series of pulses to be delivered again at the next episode

Ancillary equipment

The operational readiness of the automatic defibrillator can be tested prior to and periodically following implantation [1] by an external analyzer * This noninvasive method involves triggering the capacitor charging cycle of the defibrillator with a magnet briefly placed over the skin in the area of the implanted device After becoming fully charged the capacitors are automatically discharged into a built in test load resistor rather than through the leads to the patient The analyzer measures the charging time by means of an electromagnetic transducer Progressive increase in this time normally 10 seconds or less reflects battery depletion whereas failure to initiate the cycle indicates an abnormal condition resulting in self deactivation of the device Continuous application of the magnet over the pulse generator can be used to disable the device completely and to deplete the batteries if needed

To provide information on the long term performance of the implanted defibrillator an external recorder† is available for use in selected cases This small solid state device is triggered by the defibrillatory pulse and stores 90 seconds of ECG recording 22 5 seconds preceding and 67 5 seconds following the discharge A readout console retrieves this information and indicates the number of arrhythmic episodes the total number of pulses applied when the episode occurred and the time which elapsed since the last readout

Preclinical testing

The AID defibrillator has undergone an extensive preclinical testing program to establish its effectiveness reliability and safety In addition to acute and chronic animal electrophysiologic and pathologic studies an experimental model was designed in which the clinical syndrome of sudden death from ventricular fibrillation was reproduced in active conscious dogs [1] In these animals ventricular fibrillation was induced at will by magnetically triggering an implanted alternating current generator connected to the dog s heart through a right ventricular catheter

Table III Contribution of frequency to mortality rate in patients in Lown grade 4 or 5

Lown grade	Average VPD frequency		
	≥ 10/hr	< 10/hr	Total
Grade 4A	5/18 (28%)	3/26 (12%)	8/44 (18%)
Grade 4B	7/13 (54%)	0/8 (0%)	7/21 (33%)
Grade 5	5/53 (44%)	9/63 (14%)	34/116 (29%)
Total	37/84 (44%)	12/94 (12%)	49/181 (27%)

more VPDs per hour remained in grade 2 In either high or low frequency strata the presence of complex features caused considerable movement of patients into higher Lown grades

Complex features Complex features are arranged in a hierarchy of assumed increasing risk Fig 1 lists the Lown VPD grades across the top of the graph and the VPD characteristics on the left The hatched cells represent VPD characteristics that are unknown in each Lown grade Note that if any complex VPD characteristic (grade 3 or higher) is present VPD frequency is unknown The number of unknown VPD characteristics increases as the Lown grade becomes higher so that if a patient has even one R on T VPD all frequency and other complex features are unknown There are 33 possible combinations of the three frequency levels and four complex features In our group of 400 patients 28 of the 33 possible combinations were observed The failure to observe some of the theoretically possible combinations probably results either from low prevalence of some features e g ventricular tachycardia and/or interactions among the VPD characteristics Fig 2 shows the strength of the associations among high frequency VPDs (≥ 30 VPDs/hour) and the four complex features The strongest associations were between high frequency and pairs or ventricular tachycardia and between pairs and ventricular tachycardia For example recordings with high VPD frequency are 16 7 times as likely to contain ventricular tachycardia as those with low VPD frequency

Feinstein recommends that multiple groups be combined only if each group has a similar relationship to the target outcome We tested the homogeneity among the 16 subgroups in grade 5 with respect to mortality rate Of the 116 patients in grade 5 23 (20%) had R on T as the only complex feature the mortality rate in this group was 8 7% Also in grade 5 21 patients (18%) had

STRENGTH OF ASSOCIATION (ODDS) AMONG VPD CHARACTERISTICS

	F	M	P	V	R
F		4 9	15 1*	16 7*	3 8
M			6 2	4 8	3 8
P				19 6*	4 0
V					3 6
R					

Fig 2 The associations among VPD characteristics in 400 postinfarction patients The five characteristics used in the Lown grading system are cross associated using the odds ratio a measure of strength of association F = VPD frequency of 30/hour or greater M = multiform VPD P = paired VPD V = ventricular tachycardia R = R on T VPD Since the table is symmetric only the upper half of the matrix is given Asterisks indicate the strongest associations

all four complex features the mortality rate in this group was 62% Thus subgroups with eightfold differences in mortality rates are aggregated into Lown grade 5 We conclude that interactions among VPD characteristics significantly alter prognostic significance and that aggregation of different combinations of features into higher Lown grades obscures important information about prognosis

Lown and his colleagues currently believe that VPD frequency has little prognostic significance in patients with ischemic heart disease they believe that only grades 4 and 5 predict an adverse outcome We examined the conditional probabilities of dying given the presence or absence of a VPD frequency of 10/hour or more in Lown grades 4 and 5 these data are summarized in Table III In grades 4A 4B and 5 the proportion of patients dying was significantly greater when VPD frequency was 10/hour or greater This finding demonstrates that VPD frequency does make an important contribution to the risk of dying in patients who have repetitive or R on T VPDs In grade 5 the mortality rate when neither pairs nor ventricular tachycardia are present is 10 3% in contrast the mortality rate is 48 3% when either pairs or ventricular tachycardia are present along with R on T ($P < 0.01$) Thus R on T has little prognostic significance unless associated with repetitive VPDs

Fig 2 *Left panel* Initiation of ventricular flutter fibrillation by a burst of rapid ventricular pacing *Right panel arrow* Automatic reversion of the arrhythmia to normal sinus rhythm by the implanted defibrillator I II III aVL, aVF and V are standard ECG lead *RV* = right ventricular electrogram *FAP* = femoral artery pressure

The resulting arrhythmia leads to circulatory arrest and syncope within seconds thus creating conditions for determining the long term effects and performance of the implanted device

The preclinical testing also included the analysis of long term bench performance of the implantable defibrillator and of the effects of its exposure to various physical stresses such as vacuum pressure temperature cycling mechanical vibration mechanical shock and electromagnetic interference signals Despite the fact that many of the test conditions exceeded the standards required of implanted pacemakers the results were generally satisfactory and the few detected failure modes were analyzed and corrected The AID defibrillator also underwent an independent evaluation by the Applied Physics Laboratory of The Johns Hopkins University which included basic device design provocative challenges to the sensing system and analysis of components manufacturing and quality control procedures and preclinical test results On the basis of these data the device was found suitable for use in a clinical setting

Preliminary clinical data

A pilot study of the automatic defibrillator is presently being carried out at The Johns Hopkins Hospital in patients suffering from recurrent ventricular tachyarrhythmias refractory to medical therapy [1] Specifically the candidates for implantation must have survived at least two episodes of cardiac arrest not associated with acute myocardial infarction with ventricular fibrillation documented electrocardiographically at least once One such episode must have occurred despite treatment with a medication suppressing all complex ventricular arrhythmias present or failing that despite treatment with two conventional antiarrhythmic agents given simultaneously and resulting in satisfactory blood levels Patients were excluded if they had other chronic or acute illness were on drugs other than antiarrhythmics but known to influence electrical activity of the heart or had psychological disabilities The extremely poor prognosis of patients fulfilling these criteria is exemplified by the fact that four patients identified as potential candidates for implantations of the automatic defibrillator died before they could be transferred to The Johns Hopkins Hospital

Between February and May 1980 the first three patients underwent implantation of the automatic defibrillator This group included a 57 year old woman with coronary artery disease a 16 year old boy with idiopathic cardiomyopathy and a 43 year old man with asymmetric hypertrophic cardiomyopathy All of these patients suffered from numerous episodes of ventricular fibrillation and hypotensive ventricular tachycardia requiring multiple resuscitations and external defibrillations On electrophysiologic

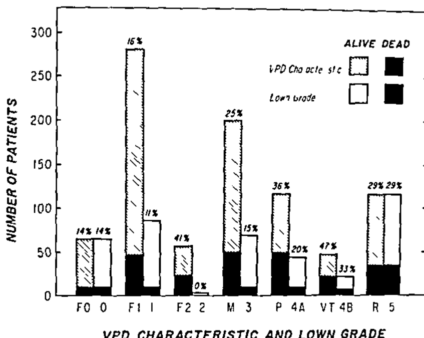

Fig 3 Comparison of VPD characteristics and Lown grades in 400 patients with ischemic heart disease Each pair of bars compares the Lown grade (right) with the characteristic that makes a person eligible for that grade *FO* = VPD frequency = 0 *F1* = VPD frequency > 0 < 30 *F2* = VPD frequency > 30 *M* = multiform VPD *P* = paired VPD *VT* = ventricular tachycardia and *R* = R on T VPD Deaths in each category are indicated by the black (lower) portion of the bars the percentages at the top of each bar represent the category specific mortality rates In grades 1 through 4B there are striking differences between the Lown grade and the characteristic that make a patient eligible for that grade

These findings serve to illustrate failings of the Lown grading system In the higher Lown grades frequency and other complex features do contribute to the risk of subsequent death The presence and intensity of these influences are hidden by the Lown grading system

Validity of the Lown grading system Feinstein has discussed criteria for judging the validity of prognostic grading systems He gives four main criteria (1) distribution of the population among the categories (2) monotonicity (3) total gradient and (4) isometry of clusters

Distribution of population When developing a grading system one hopes for a reasonably symmetric distribution among the categories with more persons in the middle than in the extreme grades Grade 2 of the Lown system presents a problem in this respect In ischemic heart disease populations less than 1% will be in grade 2 This represents a technical flaw in the Lown grading system when it is used in ischemic heart disease populations

Monotonicity If a grading system is intended to predict mortality rate then the mortality rate should increase monotonically as the grade increases If a partition (i e grade) has been ranked according to entities that do not necessarily reflect severity a monotonic trend may not occur[10] Fig 3 gives the mortality rate by Lown grade There is a notable lack of monotonicity in this grading system

Total gradient In addition to monotonicity a substantial gradient (e g 10%) between grades is desirable The Lown grading system also lacks this property There is no significant difference in the mortality rate among the first four Lown grades and there is no significant difference between the last two grades (Fig 3)

Isometry of clusters Characteristics that are combined into grades should have similar target rates As shown above subgroups with markedly different rates e g 9% to 62% are combined within grade 5 This lack of isometry will cause misclassifications that can be avoided by other grading methods In observational studies misclassification will cause confounding and mandate larger sample size and expense to detect existing relationships

Problems arising from mutually exclusive grades The mutually exclusive and hierarchical

tricular elect the fractior input elec located purpo the s dev ve s

Significantly enough two of our initial three patients were cardioverted on a few occasions by their implanted defibrillator while awake with out feeling undue discomfort or pain Occasional ly the sensation felt was so vague that only a Holter recording confirmed the automatic rever sion of the ventricular tachycardia

These preliminary results are most encouraging and demonstrate that the automatic implantable defibrillator can successfully identify and correct malignant ventricular arrhythmias in man Although many problems remain to be solved and the ultimate value of this new therapeutic modal ity has yet to be determined a new approach has become available for the prevention of sudden death in patients who are at a particularly high risk of developing malignant ventricular arrhyth mias.

grading method used by Lown does not permit investigators to relate the frequency of VPDs to other factors (e g left ventricular function) or to relate either frequency or complex VPD features to the mortality rate Fig 3 shows the prevalence of the three VPD frequency (F) strata ($F = 0$, $0 < F < 30$ and $F \geq 30$) and the four complex features used in Lown grading these categories are not mutually exclusive Note the prevalence of frequent and complex VPD features relative to the Lown grade In Fig 3 it is easy to see that frequent VPD or repetitive VPDs (pairs and ventricular tachycardia) have a very poor prognosis Also Fig [illegible] shows how the relationship between VPD frequency or complexity and death is obscured by the Lown grading system

Alternative grading systems for observational studies In the previous discussion we have detailed a number of significant problems with the Lown grading system when it is used for observational studies in ischemic heart disease The system lacks many qualities of an excellent grading system For observational studies it is better to tabulate VPD frequency and characteristics directly (Table IV) These factors can then be related to other variables e g ischemia or ventricular function or to outcome using univariate or multivariate statistical methods Such exploration should yield improved prognostic stratification and lead to a better understanding of functional interrelationships in ischemic heart disease

Use of Lown grading system for experimental studies

A grading system for evaluating antiarrhythmic action should provide an *accurate comprehensive concise* and *understandable* summary of ventricular arrhythmias on 24 hour ECG records In this section we will examine how well the Lown grading system meets these criteria

Lown arrhythmia equation To give a more detailed view of arrhythmia response to drug action Lown et al introduced an equation that describes the arrhythmia grade in each hour of a 24 hour ECG recording Lown and Graboys[?] suggested that the equation is of special value in assessing antiarrhythmic drug efficacy The Lown equation lists the Lown arrhythmia grades on a line For each Lown grade a superscript gives

Clinical use of an implantable automatic tachycardia-terminating pacemaker

Jerry C Griffin MD Jay W Mason MD and
Richard V Calfee PhD *Stanford Calif and Freeport Tex*

A significant fraction of patients with supraventricular and ventricular tachycardia remains a therapeutic problem despite improvements in diagnostic testing new drugs and improved techniques for the evaluation of the efficacy of drug therapy Pacing provides an alternative in selected patients Pacing techniques may be used for arrhythmia suppression or termination and in rare instances may allow the substitution of a more easily managed arrhythmia We have permanently implanted a new programmable automatic tachycardia terminating pacemaker in patients with drug refractory supraventricular tachycardia Following pacemaker implantation successful tachycardia termination has been documented by ambulatory monitoring Because of changing requirements for effective termination we feel programmability is mandatory for successful long term efficacy We conclude that pacemaker therapy of supraventricular trachyarrhythmia with the automatic antitachycardia terminating pacemaker is safe effective and well tolerated

A significant number of patients with supraventricular tachyarrhythmias continues to be a therapeutic problem despite improvements in diagnostic methods new drugs and new forms of surgical therapy A number of techniques for terminating these arrhythmias utilizing pacing stimuli has been described Two types of implantable pulse generators delivering bursts of rapid atrial stimuli have been available for several years[2,3] One is adjustable but must be activated by the patient The other responds automatically to a tachycardia but is made to prescription and is not adjustable There is now available a new automatic tachycardia detecting and terminating pacemaker which is multiprogrammable allowing preimplant and noninvasive postimplant alteration of a wide range of pacemaker functions We have utilized this system for treating tachyarrhythmias in patients referred to Stanford University Medical Center

Patient selection

Patients were considered for pacemaker therapy if they were drug refractory or their tachycardia was controlled only at the expense of significant drug side effects All were adults and all were evaluated by invasive electrophysiologic study Particular emphasis was placed on the detection of extranodal pathways Patients with rapidly conducting anterograde pathways were not considered good candidates for pacing therapy because of two potential hazards (1) The induction of atrial fibrillation resulting in rapid A V conduction and (2) 1 1 A V conduction of the terminating burst In each patient consistently reliable arrhythmia termination had to be demonstrated repeatedly on more than one day

The tachycardia terminating pacemaker

The pacemaker the Cybertach 60 manufactured by Intermedics Inc is a multiprogrammable bipolar lithium powered device measuring 6 × 4 6 × 1 5 cm and weighing 95 gm It functions as a standard inhibited pacemaker with the capacity to automatically respond to tachyarrhythmias The tachycardia terminating response may be inhibited noninvasively Other programmable variables include two basic pacing rates (60 and 80 beats/min) 15 pulse durations (0 15 to 2 29 msec) and seven input sensitivity levels (0 6 to 2 8 mV) The automatic tachycardia terminating features are also programmable Twenty eight combinations of burst rate and duration are available ranging from 180 to

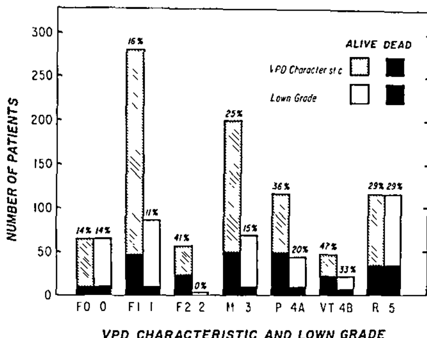

Fig 3 Comparison of VPD characteristics and Lown grades in 400 patients with ischemic heart disease Each pair of bars compares the Lown grade (right) with the characteristic that makes a person eligible for that grade *FO* = VPD frequency = 0 *F1* = VPD frequency > 0 < 30 *F2* = VPD frequency > 30 *M* = multiform VPD *P* = paired VPD *VT* = ventricular tachycardia and *R* = R on T VPD Deaths in each category are indicated by the black (lower) portion of the bars the percentages at the top of each bar represent the category specific mortality rates In grades 1 through 4B there are striking differences between the Lown grade and the characteristic that make a patient eligible for that grade

These findings serve to illustrate failings of the Lown grading system In the higher Lown grades frequency and other complex features do contribute to the risk of subsequent death The presence and intensity of these influences are hidden by the Lown grading system

Validity of the Lown grading system Feinstein[1] has discussed criteria for judging the validity of prognostic grading systems He gives four main criteria (1) distribution of the population among the categories (2) monotonicity (3) total gradient and (4) isometry of clusters

Distribution of population When developing a grading system one hopes for a reasonably symmetric distribution among the categories with more persons in the middle than in the extreme grades Grade 2 of the Lown system presents a problem in this respect In ischemic heart disease populations less than 1% will be in grade 2 This represents a technical flaw in the Lown grading system when it is used in ischemic heart disease populations

Monotonicity If a grading system is intended to predict mortality rate then the mortality rate should increase monotonically as the grade increases If a partition (i e grade) has been ranked according to entities that do not necessarily reflect severity a monotonic trend may not occur[10] Fig 3 gives the mortality rate by Lown grade There is a notable lack of monotonicity in this grading system

Total gradient In addition to monotonicity a substantial gradient (e g 10%) between grades is desirable The Lown grading system also lacks this property There is no significant difference in the mortality rate among the first four Lown grades and there is no significant difference between the last two grades (Fig 3)

Isometry of clusters Characteristics that are combined into grades should have similar target rates As shown above subgroups with markedly different rates e g 9% to 62% are combined within grade 5 This lack of isometry will cause misclassifications that can be avoided by other grading methods In observational studies misclassification will cause confounding and mandate larger sample size and expense to detect existing relationships

Problems arising from mutually exclusive grades The mutually exclusive and hierarchical

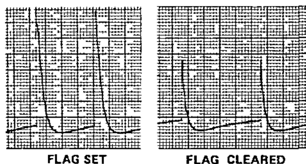

Fig 1 An electronic flag" is set in the pacemaker circuitry when a tachycardia is sensed producing the telemetry artifact seen in the left trace After reprogramming this flag is removed (small artifact)

pulses for 1 3 to 5 4 seconds The presence of an arrhythmia is determined by rate and the criteria are programmable (greater than 137 or 180 beats/min) Input signals with a frequency greater than 350/min are defined as noise no tachycardia terminating response is delivered and asynchronous pacing is initiated Application of a magnet converts the device to an asynchronous pacemaker without the tachycardia terminating response

This pacemaker also has the capacity to collect data regarding the occurrence of tachyarrhythmias to store it and to telemeter it upon command to the evaluating physician A large amplitude telemetry artifact indicates that the pacemaker has sensed a tachycardia since the last programming (Fig 1) Reprogramming or simply placing a magnet over the pacemaker clears this flag producing a small amplitude artifact The pacemaker may be interrogated directly by means of the programmer or by transtelephonic monitoring

Programmability has been important in maintaining proper pacemaker function in patients implanted with the Cybertach 60 Frequently the burst rate most effective for termination changed after the patient was ambulatory and fully recovered from the effects of hospitalization and previous drug therapy Maintenance of optimal pacing and sensing levels also necessitated adjustment of pulse duration and sensitivity level These units have been implanted by means of a transvenous tined bipolar atrial J electrode Following interpretation patients are monitored continuously and the pacemaker response to spontaneous arrhythmia is noted If adequate documentation of effective termination is not established by 72 hours the patient is returned to the electrophysiology laboratory and the arrhythmia is induced (Fig 2) Periodic 24 hour Holter monitoring is carried out in each patient to document efficient termination (Fig 3) Each patient keeps a log of the occurrence of symptoms of tachyarrhythmia If no symptoms have occurred the absence of arrhythmia is verified by interrogating the telemetry system of the pacemaker

The role of automatic pacing termination

Since the initial description by Haft et al [4] termination of supraventricular tachyarrhythmias by pacing techniques has received steadily increasing interest A variety of approaches to the management of supraventricular tachycardia by pacing techniques has been described including single random extrastimuli [7] simultaneous A V sequential pacing [9] dual demand pacing [1] orthorhythmic pacing [1] and scanning [8] In a comparison of a variety of techniques Fisher et al [3] demonstrated the greater effectiveness of bursts of rapid atrial stimulation at rates greater than 30 beats/min faster than the tachyarrhythmia Patient activated implantable devices capable of delivering bursts of rapid atrial stimuli are available and their efficacy in the chronic therapy of supraventricular tachyarrhythmias has been demonstrated [5, 6, 1, 1]

These systems do however have several shortcomings (1) They require that the patient be able to perceive both the presence and absence of tachyarrhythmia (2) They do not provide for a uniform burst duration since this is controlled by the patient (3) They require that the patient have constant access to a transmitter in the event that tachycardia should occur (4) They deliver a large amount of pacing energy to the myocardium (usually greater than 8 volts) (5) They are not effective in patients rapidly disabled by their tachyarrhythmia (6) They leave a significant residue of symptoms in patients with frequently recurring symptomatic tachycardia due to the time period necessary to perceive the arrhythmia and apply the transmitter

Custom built rapid atrial stimulators possess several advantages over radiofrequency devices in that the burst pattern is consistent in terms of energy output and burst duration In addition they provide for automatic recognition and anti

ramine (Fig 4) Fig 4 permits a comparison of th[illegible] number of hours assigned each Lown grad[illegible] (above) to the actual number of hours containin[illegible] each VPD characteristic (below) Prior to treat ment the patient has Lown grade 5 in 15 of the 2[illegible] hours recorded Lown grades 4A and 4B occur i[illegible] hours each although in reality VPD pairs [illegible] in 19 hours and ventricular tachycardia [illegible] hours There are 4 hours in Lown gra[illegible] although the patient actually has [illegible] VPDs in all but 1 hour of the 24 hour re[illegible] There are no Lown grade 2 hours howe[illegible]er [illegible] are more frequent than 30/hour during 16 [illegible] 24 hours in the pretreatment tape This di[illegible] is accounted for by the strong asso[illegible] between a VPD frequency of ≥ 30 hou[illegible] complex VPD features Because of th[illegible] tion the Lown equation provides almost no in[illegible] mation concerning VPD frequency in th[illegible] treatment record

Analysis of the response to imipramine t[illegible] (Fig 4) shows that the Lown grading syst[illegible] also inadequate for judging the efficacy of antiarrhythmic therapy Imipramine mar[illegible]edly decreases both VPD frequency and complex VPD features (Fig 4 bottom) The Lown grades (Fig 4 top) do not accurately reflect this response of VPD frequency and VPD complexity to imipra mine For example Lown grade 3 hours increase during the first day of imipramine therapy (Fig 4 top) even though there is a progressive decrease in the hours containing multiform VPDs (Fig 4 bottom) Similarly grade 2 hours show no change even though hours with frequent VPDs (≥ 30 hour) decrease markedly on the first day of imipramine treatment and then disappear entire ly Thus the Lown grading system may provide only limited insight into the magnitude or even the direction of the response of individual VPD characteristics to antiarrhythmic therapy

We contend that a few simple modifications of the Lown arrhythmia equation provide a much more valuable tool for evaluating the response of ventricular arrhythmias to therapy We recom mend the following changes (1) count the actual VPD characteristics rather than Lown grades (2) count each complex VPD feature independent of VPD frequency or any other complex VPD features and (3) use subscripts for VPD charac teristics that apply to *all* hours of the ECG recording We replace Lown grades 0 1 and 2 with a single frequency category F The first superscript (prehyphen) for F is the number of

[illegible] cord [illegible] of data [illegible] d The [illegible] fre[illegible] d for [illegible] in all [illegible] Lown grad[illegible] 4A [illegible] for [illegible] for VPD [illegible] ventricul[illegible]r [illegible] P for [illegible] VPD [illegible] count [illegible] the VPD characteristic occu[illegible] to M is the number of different VPD configurations on the entire ECG recording and the subscripts to P V and R refer to the total number of the e events in the ECG record [illegible] use a econd subscript to R to give the shor[illegible] R V/Q T interval in the ECG recording

To compare our notation to the Lown arrhyth mia equation we compared the three ECG records in Fig 4

The subscript of the F category (average VPDs per hour) in our notation accurately shows the pronounced drop in VPD frequency during imip ramine therapy whereas the Lown equation does not Our notation permits rapid calculation of the *total* number of VPDs (F superscript multiplied by F subscript) The Lown arrhythmia equation *does* not permit calculation of average VPD frequency or of total VPDs in an ECG recording *Our* notation reveals the progressive decrease in multiform VPDs during treatment Lown grade 3 does not reveal this response Also our notation clearly enumerates the repetitive activity in the ECG recordings whereas Lown grades 4A and 4B do not For these rea ons, we feel that the modi

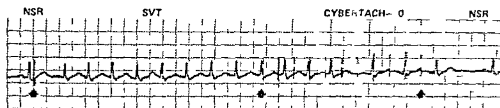

Fig 2 Illustrating the function of the tachycardia terminating pacemaker On the left hand portion of the continuous ECG strip the rhythm is sinus A single premature extrastimulus is placed during the relative refractory period of the A V node inducing supraventricular tachycardia After counting eight consecutive intervals shorter than the programmed tachycardia criteria the pacemaker responds with a burst of rapid stimuli that terminate the arrhythmia restoring normal sinus rhythm

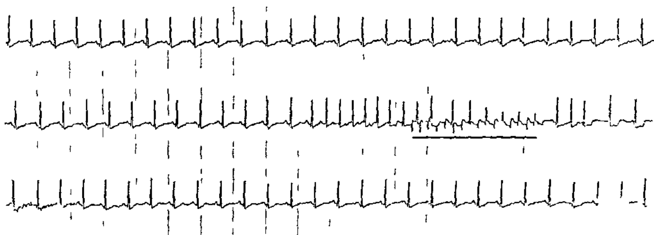

Fig 3 Tracing taken from a 24 hour Holter monitor study illustrates the termination of a spontaneous episode of supraventricular tachycardia The upper tracing shows 20 seconds of normal sinus rhythm The middle tracing shows normal sinus rhythm followed by ? beats of supraventricular tachycardia The tachycardia terminating pacemaker is then activated for 4 seconds ?40 pulses/min after which sinus rhythm is restored

tachycardia response freeing the patient from the problems of keeping a transmitter available and applying it after the onset of symptoms However these units possess significant disadvantages when compared to the programmable automatic burst pacemaker There is a significant delay once the decision for pacing therapy is made to have a device adjusted and furnished to the implanting physician Most important this type of unit does not allow subsequent flexibility to respond to changes in pacemaker requirements We have found significant changes in the requirements for optimal burst termination between the artificial setting of the catheterization laboratory and the chronic circumstance of an ambulatory patient with a chronically implanted electrode

The atrial stimulator used in our patients is extensively programmable and fully automatic It responds with a burst of stimuli at a uniform rate and duration after sensing eight consecutive RR intervals sufficiently brief in duration to meet the program criteria for the definition of tachycardia For a tachycardia of 150 beats/min less than 6 seconds is usually required for sensing and termination Therefore patients are usually only transiently aware if at all of the presence and termination of tachycardia

Due to the extensive programmability follow up evaluation of these patients can be quite complete At each clinic visit thresholds for pacing and sensing in normal sinus rhythm are determined In certain patients with easily inducible arrhythmias pacemaker efficacy can be tested by the application of a magnet This produces single random extrastimuli which eventually will initiate an episode of tachycardia

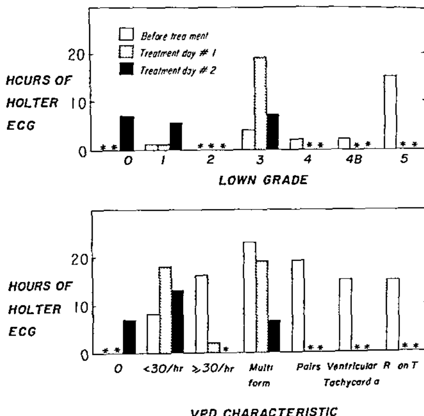

Fig 4 The use of the Lown grading system to summarize the results of an antiarrhythmic drug trial with imipramine Above the Lown system is used to summarize the findings in three 24 hour Holter ECG recordings tape 1 = pretreatment tape 2 = lower dose and tape 3 = higher dose Below the same three tapes have been summarized by tabulating all hours containing the VPD characteristic only the frequency characteristics are mutually exclusive An asterisk indicates that the Lown grade or the VPD characteristic was not present in any hour of the recording The Lown grades do not accurately reflect the hourly count for VPD characteristics (see below) and do not accurately reflect the response of VPD characteristics to therapy

the number of hours in the 24 hour ECG recording which is assigned to that grade Subscripts further characterize some Lown grades for grade 2 the subscript gives the number of VPDs in the grade 2 hours for grade 3 the subscript denotes the maximum number of VPD configurations observed in any single grade 3 hour for grade 4A the subscript gives the maximum number of VPD pairs in any grade 4 hour for grade 4B the first subscript refers to the maximum number of episodes of ventricular tachycardia in a single grade 4B hour while the second subscript indicates the number of cycles in the longest run of ventricular tachycardia for grade 5 the subscript identifies the maximum number of R on T VPDs occurring in any grade 5 hour

The Lown equation has several ambiguities and drawbacks First no account is given of the noise that frequently occurs in ambulatory ECG recordings Noise reduces the VPD count and if an adjustment is not made the calculated VPD frequency will be too low Noise also increases the likelihood of false positive VPDs Both of these effects make noise important to report Second the equation makes it difficult to determine VPD frequency or other VPD characteristics In the Lown grades a subscript applies only to the hours assigned to its grade [13] Thus if five VPD configurations exist in a 24 hour ECG recording but only two appear in any grade 3 hour the subscript for grade 3 will be 2 not 5 Similarly the subscript to grade 2 does not count the VPDs occurring in higher grades This convention makes it impossible to calculate VPD ency d for a 24 hour ECG recording Third is given for grade 1 therefore th VPDs in Lown grade 1 hours

To illustrate the use of intervention trials we and individual VPD ch ambulatory ECG record undergoing anti

Pacing and sensing thresholds can then be deter mined during tachycardia Several burst patterns can be tested and the most effective one deter mined

We feel pacing has significant advantages when compared with pharmacologic therapy With antiarrhythmic drugs adverse effects are com mon frequently resulting in significant morbidity and occasional death The patient is freed from the nuisance of taking multiple doses of medica tion each day Pacing may be an especially effec tive form of therapy for those patients who are unreliable Pacing for supraventricular arrhyth mias of course carries some complications as well It requires a surgical procedure for implan tation and carries with it all the usual complica tions of pacemaker implantation In addition patients treated in this way are at risk of the induction of atrial fibrillation which if persistent may require cardioversion

This pacemaker provides safe and effective therapy for supraventricular tachyarrhythmias It is most applicable in those patients unrespon sive to pharmacologic therapy unaware of the presence of supraventricular arrhythmias and/or rapidly disabled by their tachycardias Tachycar dia therapy with the automatic tachycardia terminating pacemaker has a high level of patient acceptance due to the freedom from the expense side effects and nuisance of drug therapy

ramine (Fig 4) Fig 4 permits a comparison of the number of hours assigned each Lown grade (above) to the actual number of hours containing each VPD characteristic (below) Prior to treatment the patient has Lown grade 5 in 15 of the 24 hours recorded Lown grades 4A and 4B occur in 2 hours each although in reality VPD pairs occur in 19 hours and ventricular tachycardia in 15 hours There are 4 hours in Lown grade 3 although the patient actually has multiform VPDs in all but 1 hour of the 24 hour record There are no Lown grade 2 hours however VPDs are more frequent than 30/hour during 16 of the 24 hours in the pretreatment tape This disparity is accounted for bv the strong association between a VPD frequency of ≥ 30/hour and complex VPD features Because of this association the Lown equation provides almost no information concerning VPD frequency in the pretreatment record

Analysis of the response to imipramine therapy (Fig 4) shows that the Lown grading system is also inadequate for judging the efficacy of antiarrhythmic therapy Imipramine markedly decreases both VPD frequency and complex VPD features (Fig 4 bottom) The Lown grades (Fig 4 top) do not accurately reflect this response of VPD frequency and VPD complexity to imipramine For example Lown grade 3 hours increase during the first day of imipramine therapy (Fig 4 top) even though there is a progressive decrease in the hours containing multiform VPDs (Fig 4 bottom) Similarly grade 2 hours show no change even though hours with frequent VPDs (≥ 30/hour) decrease markedly on the first day of imipramine treatment and then disappear entirely Thus the Lown grading system may provide only limited insight into the magnitude or even the direction of the response of individual VPD characteristics to antiarrhythmic therapy

We contend that a few simple modifications of the Lown arrhythmia equation provide a much more valuable tool for evaluating the response of ventricular arrhythmias to therapy We recommend the following changes (1) count the actual VPD characteristics rather than Lown grades (2) count each complex VPD feature independent of VPD frequency or any other complex VPD features and (3) use subscripts for VPD characteristics that apply to *all* hours of the ECG recording We replace Lown grades 0 1 and 2 with a single frequency category F The first superscript (prehyphen) for F is the number of consecutive hours of ECG analyzed the second (posthyphen) superscript shows the hours of data loss due to noise in the hours analyzed The subscript for F is the average hourly VPD frequency for all hours analyzed (adjusted for noise) This new notation (1) clearly indicates 24 hour average VPD frequency (2) avoids dichotomizing at an arbitrary frequency value (3) condenses all frequency information into a single category and (4) accounts for data loss due to noise Accounting for data loss permits the investigator to correct the observed counts in all categories We have replaced Lown grades 3 4A 4B and 5 with M P V and R respectively M for multiform P for VPD pairs V for ventricular tachycardia and R for R on T VPD In our notation superscripts represent a count of *all* hours in which the VPD characteristic occurs The subscript to M is the number of different VPD configurations on the entire ECG recording and the subscripts to P V and R refer to the total number of these events in the ECG record We use a second subscript to R to give the shortest R V/Q T interval in the ECG recording

To compare our notation to the Lown arrhythmia equation we compared the three ECG record in Fig 4

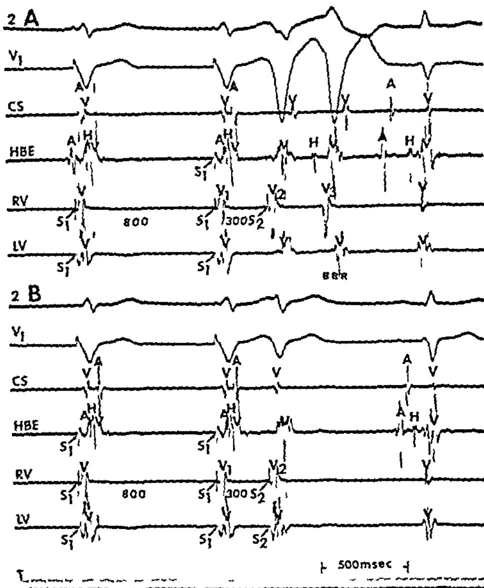

Fig. 6. Prevention of bundle branch reentry by simultaneous right and left ventricular stimulation. The figure is organized as *Fig. 4*. In *panel A*, a right ventricular premature stimulus (S_2) is delivered at a coupling interval of 300 msec during ventricular pacing (S_1-S_1) at a cycle length of 800 msec, resulting in bundle branch reentry (*BBR*) as previously described. In *panel B* simultaneous right and left ventricular stimulation at the same coupling intervals as in panel A failed to induce BBR. Simultaneous stimulation of the opposite ventricle renders the retrograde limb of the BBR pathway (LV conduction system) refractory, thereby abolishing reentry.

of the patients with documented ventricular tachycardia/fibrillation had only bundle branch reentry.

Characteristics of repetitive ventricular responses. Bundle branch reentry usually had a configuration similar to the ventricular paced complex that initiated this response at longer coupling intervals (i.e., right bundle branch block pattern for left ventricular premature stimuli and left bundle branch pattern for right ventricular premature stimuli) (Figs. 1 and 4). However, changes in morphology were observed at very close coupling intervals. Regardless of the ventricle of stimulation, bundle branch reentry occurred only when a critical degree of V-H delay was attained. The range of retrograde His-Purkinje conduction delay (V-H interval) required for initiation was 160 to 300 msec. In most

Table II

	VT/VF (58 pts)	RBBB (35 pts)	LBBB (17 pts)
BBR	29	2	1
IVR	43	20	8
None	8	14	8

BBB = bundle branch block R = right L = left BBR = bundle branch reentry IVR = intraventricular reentry VT/VF = ventricular tachycardia/ventricular fibrillation

patients demonstrating bundle branch reentry this response was elicited with a single premature ventricular stimulus during ventricular pacing in 11 patients (5%) double premature ventricular stimuli were required

The degree of retrograde His Purkinje conduction delay produced during ventricular stimulation was the same in patients who developed bundle branch reentry as in those who failed to develop this phenomenon The presence or absence of organic heart disease was not related to the appearance of retrograde conduction delay However retrograde conduction delay was only noted in 12 of the 35 (34 3%) patients with right bundle branch block and was observed in 296 patients (85%) without conduction delay

There was a direct relationship between paced cycle length and the coupling interval of bundle branch reentrant complexes This was related to a longer His Purkinje refractory period at the longer paced cycle length therefore facilitating the development of retrograde His Purkinje delay in response to ventricular extrastimuli No bundle branch reentry was observed during retrograde gap phenomena In addition bundle branch reentry did not occur when spontaneous or stimulated supraventricular complexes pre excited the His bundle antegradely prior to the time it would have been engaged retrogradely during ventricular extrastimuli (Fig 5) or when ventricular extrastimuli were delivered simultaneously in both ventricles (Fig 6) Bundle branch reentry produced one to four extra complexes but was never sustained

In contradistinction to responses due to bundle branch reentry intraventricular reentrant complexes appearing after single (63 patients 81%) or only after double ventricular extrastimuli (15 patients 19%) frequently had a configuration distinctly different from that of the paced ventricular complex Intraventricular reentry occurred in the absence of definite retrograde H potentials in approximately 80% of patients with these responses, and with H V intervals shorter than those in sinus rhythm in the remainder (16 patients) Intraventricular reentry most often occurred during stimulation within 25 msec of the ventricular refractory period however in 20 patients with ventricular tachycardia or ventricular fibrillation there was a zone of at least 50 msec prior to ventricular refractoriness when the intraventricular reentrant complexes were noted. In patients who subsequently developed sustained ventricular tachycardia the intraventricular reentrant complex resembled the configuration of the complexes during ventricular tachycardia regardless of the site of stimulation (Fig 2) In three patients ventricular tachycardia was only inducible with programmed electrical stimulation of the left ventricle In these three patients intraventricular reentrant complexes were only elicited with left ventricular stimulation and occurred with right bundle branch block morphologies Supraventricular stimuli did not prevent intraventricular reentry nor did biventricular stimulation prevent it in ten patients in whom these perturbations were attempted

In patients who demonstrated both bundle branch reentry and intraventricular reentry the zones of coupling intervals which produced each were different although some overlap appeared In ten cases bundle branch reentrant complexes acted as a secondary ventricular premature extrastimulus inducing intraventricular reentry When this was observed the bundle branch reentry occurred at coupling intervals similar to those found capable of inducing intraventricular reentry with double premature ventricular extrastimuli In seven patients intraventricular reentry was associated with the appearance of unrelated retrograde His potentials

Of the 19 patients who had ventricular fibrillation prior to study four had no demonstrable organic cardiac disease, only one of these four had intraventricular reentry and this patient was the only one of the four with inducible ventricular fibrillation Of the 15 patients with heart disease and ventricular fibrillation 11 had intraventricular reentrant complexes eight of these 11 had inducible ventricular fibrillation In each case these intraventricular reentrant complexes were

branch block morphology rarely developed bundle branch reentry[1,4] This appears to reflect prolonged retrograde as well as antegrade conduction and refractoriness[1,4,7] However, a higher than expected percentage of patients with bundle branch block developed intraventricular reentry (55% versus 19%) Therefore not surprisingly, a high incidence of ventricular arrhythmias has been reported in patients with such conduction disturbances, and ventricular fibrillation rather than heart block has been suggested as the cause of sudden death in many of these patients[8,9] These relationships provide further support that intraventricular reentry is a marker for those patients prone to develop malignant ventricular tachyarrhythmias

In conclusion two different mechanisms of repetitive ventricular responses encountered during ventricular stimulation exist One bundle branch reentry involves a macroreentrant circuit involving the bundle branches and is a benign phenomenon occurring in more than half the patients in whom ventricular stimulation is carried out Intraventricular reentry on the other hand represents a pathological event closely related to clinical ventricular arrhythmias

Summary

Repetitive ventricular responses (RVR) to programmed ventricular stimulation were observed in 238 of 400 patients (59 5%) Two types of RVR with different mechanisms and clinical significance in relation to ventricular arrhythmias could be identified

1 Repetitive ventricular responses resulting from bundle branch reentry occurred in 53% of patients without any significant difference of incidence in the presence (52 9%) or absence (54 1%) of organic heart disease

2 Repetitive ventricular responses resulting from intraventricular reentry occurred in 19 5% of patients with a significantly higher incidence in patients with (23 9%) than without (8 1%) organic heart disease Thirty eight of 41 (92 7%) patients with inducible ventricular tachycardia or fibrillation also had intraventricular reentry but only 9 1% of patients without these arrhythmias manifested intraventricular reentry ($p < 0\ 005$) Moreover the mode of induction and the configuration of intraventricular reentry was closely related to that of ventricular tachycardia when induced

It is concluded that bundle branch and intraventricular reentry are different phenomena both in mechanism and relationship, to spontaneous ventricular arrhythmias Bundle branch reentry appears to be a benign phenomenon which represents a physiological response of the His Purkinje system and is not directly related to ventricular arrhythmias On the other hand our data suggest that intraventricular reentry may be a 'pathologic phenomenon closely related to ventricular arrhythmias The presence of intraventricular reentry may identify patients who are prone to develop ventricular tachycardia or fibrillation

multiple (≥ three complexes) and were often polymorphic, resembling so-called *torsade de pointe*.

Of the 39 patients who had sustained ventricular tachycardia, nine had no organic cardiac lesion; only four of these nine patients had inducible ventricular tachycardia and three of these four had intraventricular reentries. Of the 30 patients with known cardiac disease, 28 had inducible ventricular tachycardia and 26 of these 28 had intraventricular reentries. Intraventricular reentry did not necessarily occur at the same drive cycle length (S_1S_1) that was utilized during induction of ventricular tachycardia, and reentrant complexes occurred with single extrastimuli in five patients who required double ventricular extrastimuli for initiation of ventricular tachycardia. Two patients with noninducible ventricular tachycardia also had intraventricular reentry. Conversely, of 78 patients demonstrating intraventricular reentry, 43 had documented spontaneously occurring sustained ventricular tachycardia or ventricular fibrillation; 38 of these 43 had inducible ventricular tachycardia or fibrillation in the electrophysiologic laboratory as well.

Thirty-five patients in this study had right bundle branch block pattern on their surface electrocardiogram; all were in sinus rhythm. Only two of these patients demonstrated bundle branch reentry; 21, however, developed intraventricular reentrant complexes. Of 17 patients with left bundle branch block, only one had bundle branch reentry and eight had intraventricular reentry.

Discussion

Repetitive ventricular responses are a frequent accompaniment of ventricular stimulation. Such repetitive responses were noted in 59.5% of 400 consecutively studied patients. The most common form of repetitive response was that due to bundle branch reentry. As suggested by previous workers,[1] bundle branch reentry was observed in normal individuals as frequently as it was in those with organic heart disease. Wellens and colleagues[3] and Josephson and associates[4] observed that bundle branch reentry rarely if ever caused sustained ventricular tachycardia, and this was true in the present study, in which no patient developed sustained bundle branch reentry as the mechanism of sustained ventricular tachycardia. Thus macroentry involving the bundle branches (the mechanism postulated for bundle branch reentry) does not appear to be a cause of sustained spontaneous or induced ventricular arrhythmias. However, bundle branch reentrant complexes may act as additional extrastimuli inducing sustained ventricular tachycardia or intraventricular reentry. Wellens and co-workers[3] observed that in six of 29 patients with inducible ventricular tachycardia the initial complex (V_3) was different in morphology from subsequent complexes and in some cases this initial complex was undoubtedly a bundle branch reentry.

Intraventricular reentry appeared far more commonly in patients with organic heart disease than in patients with normal hearts and was associated with the presence of more malignant forms of ventricular dysrhythmias. Of 78 patients with either isolated intraventricular reentry or intraventricular reentry associated with bundle branch reentry, 43 had documented sustained ventricular tachycardia and/or fibrillation. Furthermore, the frequency of intraventricular reentry in patients with significant ventricular arrhythmias was 74%, whereas it was 9.1% in patients without such arrhythmias ($p < 0.001$). While the patient population with intraventricular reentry contained a higher percentage of patients with documented or suspected ventricular tachycardia/fibrillation, the fact that this form of repetitive response, especially when multiple, was to a large extent confined to this group of patients suggests that a relationship between the two does exist.

Intraventricular reentry probably results from reentry within the ventricular myocardium and distal His-Purkinje system. This may occur locally in proximity to the site of stimulation or at a distance and in relation to anatomic or ischemic lesions (especially in the left ventricle). Our data suggest that large segments of the proximal His-Purkinje system are not required. Unlike bundle branch reentry, intraventricular reentry cannot be prevented by appropriately time supraventricular impulses which pre-excite the bundle of His. Furthermore, the dissociation between His bundle electrograms and intraventricular reentrant responses suggests that the proximal His-Purkinje system does not form a portion of the reentrant pathway.

As noted previously, patients with bundle

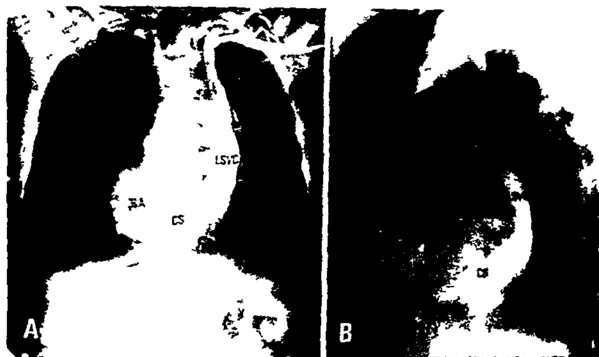

Fig 1 Biplane angiocardiograms of the PLSVC in a 23-year-old female patient with associated ASD *Panel A* is the frontal view and *panel B* is the lateral view The PLSVC is clearly demonstrated both in the frontal and lateral view of the chest. It runs along the left side of the sternum posterior to the left atrium as a narrow tubular shadow Abbreviations *RA* = right atrium *CS* = coronary sinus LSVC = left superior vena cava.

Persistent left superior vena cava (PLSVC) is essentially not a serious cardiac malformation producing severe cardiac symptoms by itself However if this lesion can be detected noninvasively the burden on patients would be less at cardiac catheterization and surgical intervention In addition it would be possible to differentiate the abnormalities emanating from the left atrium and/or the boundary between the left ventricle and the left atrium noninvasively

Echocardiography has proved to be useful to analyze the cardiac movement and anatomical abnormalities and to estimate the cardiac function in various congenital and acquired heart diseases Echocardiographic findings of enlarged coronary sinus communicating with an anomalous vein have been reported by a few clinicians using M mode echocardiography but the echo source of the coronary sinus was not fully analyzed In addition a study on PLSVC with cross sectional echocardiography has yet to be reported The purpose of this study is to describe our attempt at the noninvasive diagnosis of the PLSVC using high speed cross sectional echocardiography with mechanical sector scanning combined with an M mode system

Materials and methods

Twelve patients underwent high speed cross sectional echocardiography with a real time mechanical imaging system Ages ranged from 1 to 37 years Four patients were male and eight were female Cardiac catheterization combined with angiocardiography was performed on all 12 patients before or after cross sectional echocardiographic examination The main associated cardiac malformations of the examined patients are shown in Table I Seven of the patients underwent surgical repair for main cardiac malformations but the PLSVC was not operated on

Cross sectional and M mode echocardiograms were obtained using a Toshiba Model SSL 51H Sonolayergraph as previously reported by our laboratory This instrument has a 3 MHz 10 mm transducer focused at 75 mm with a repetition rate of 3 6 kHz Sector speed was 30 cross sections per second and sector angle was changed from 30 degrees to a maximum of 90 degrees but it was usually observed with the fixed angle of 80 degrees To enable the identification of the echo source a certain scanning line was manually selected and B mode was switched to M mode to obtain the M mode echocardiogram

The patients were examined in the supine position The transducer was immersed in a castor oil bath placed on the chest surface over the third or the fourth intercostal space at the left sternal border The so called proximity immersed method was employed[6]

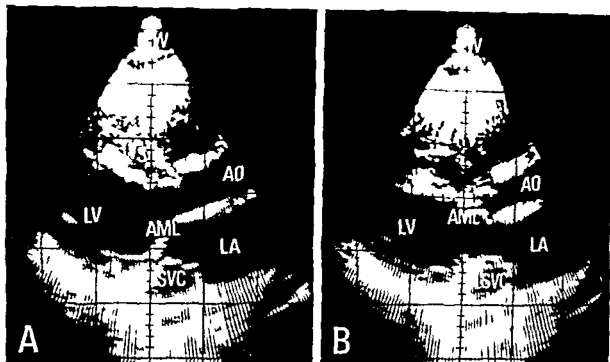

Fig 3 Cross sectional echocardiograms of a long cardiac axis in a 24 year old female patient having PLSVC with ASD *Panel A* is an image of systole and *panel B* is recorded in early diastole An unusual circular echo is recognized at the boundary between the left atrium and the left ventricle Its circular echo shows an almost complete round form Abbreviations *CW* = chest wall *RV* = right ventricle *IVS* = interventricular septum *AO* = aorta *LA* = left atrium *LV* = left ventricle *AML* = anterior mitral leaflet *LSVC* = left superior vena cava

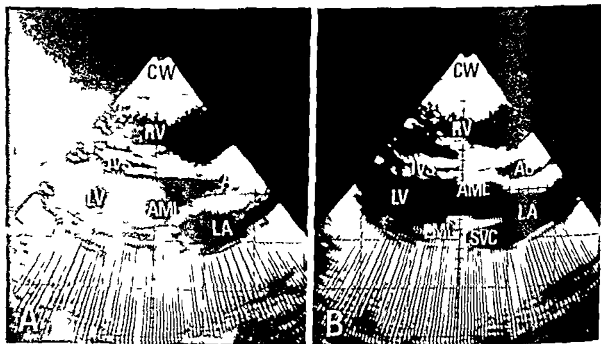

Fig 4 Cross sectional echocardiograms in the long cardiac axis in a 4 year old female patient having PLSVC with ASD and MI *Panel A* is recorded in systole and *panel B* in diastole The circular echo is presented posterior to the PML and it is larger in diastole than in systole The echo discontinuity is recognized at the upper portion of the circular echo Abbreviation *CW* = chest wall *RV* = right ventricle *IVS* = interventricular septum *AO* = aorta *LA* = left atrium *LV* = left ventricle *AML* = anterior mitral leaflet *PML* = posterior mitral leaflet *LSVC* = left superior vena cava

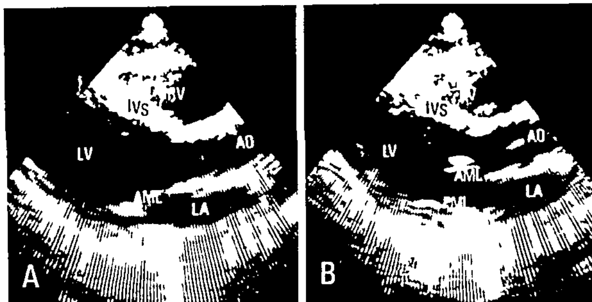

Fig 2 Cross sectional echocardiograms along the long cardiac axis in a normal subject *Panel A* is recorded in systole and *panel B* shows the early diastolic image of the heart The posterosuperior region of the PML is solid wall tissue and revealed no abnormal findings Abbreviations *RV* = right ventricle *AO* = aorta *IVS* = inter ventricular septum *AML* = anterior mitral leaflet *PML* = posterior mitral leaflet *LA* = left atrium *LV* = left ventricle

along the long cardiac axis the sagittal and the horizontal planes of the chest In some patients only one or two cross sections were analyzed

Results

Fig 1 shows the biplane angiocardiograms obtained by the injection of the contrast material from the left subclavian vein in patient No 2 having PLSVC associated with ASD The PLSVC is demonstrated posterior to the left atrium along the left side of the sternum as a narrow tubular image and it opens to the enlarged coronary sinus in the right atrium Thus the PLSVC seems to run along the left atrioventricular sulcus

The cross section of the long cardiac axis demonstrated the relationship between the aorta and two left sided heart chambers The posterior region of the posterior mitral leaflet (PML) usually appears as a solid wall echo in the normal subject (Fig 2) No abnormal echo was recognized at this region

In the patients with PLSVC a circular echo was recognized at the boundary between the left atrium and the left ventricle in the cross section of the long cardiac axis Fig 3 shows the cross sectional echocardiograms along the long cardiac axis in a 24 year old female having PLSVC with ASD A circular echo having an echo free space is clearly demonstrated at the posterosuperior region of the PML In this patient the circular echo has an almost complete form without echo discontinuity According to the real time observation a circular echo was gradually enlarged during systole and it was largest in early diastole at the E point of the anterior mitral leaflet (AML) and contracted in mid diastole In a 4 year old girl with PLSVC the circular echo was also recognized in the same region as in Fig 3 (Fig 4) However the upper part of this echo seems to show an echo discontinuity and to open into the left atrium In the majority of the examined patients the echo discontinuity was recognized at the upper part of the circular echo It is most likely that the echo discontinuity occurred because the echo beam went parallel to the wall of the PLSVC

When the scanning line was selected to the circular echo to obtain the M mode echocardiogram an unusual linear echo with the shallow space was recorded behind the AML Fig 5 presents the M mode scan echocardiograms obtained from patients No 1 2 3 and 6 The AML shows almost normal movement and the diastolic descent rate (DDR) of the AML was also within normal limits The unusual linear echo was demonstrated posterior to the AML but it appeared neither in the left ventricle nor in the left atrium This linear echo gradually moved

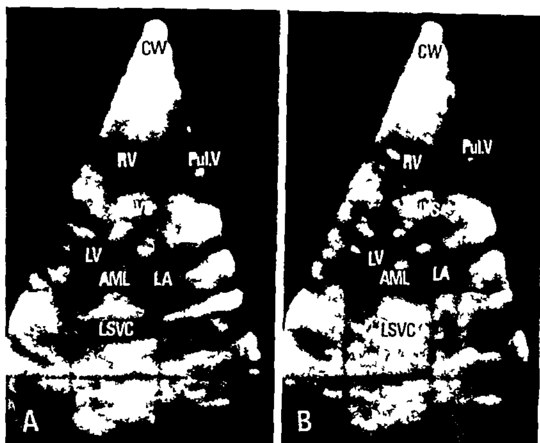

Fig 6 Cross sectional echocardiograms in the patients with PLSVC before (*A*) and after (*B*) dye injection These pictures were recorded along the cross section of the sagittal plane of the chest An echo free space is recognized posterior to the two left sided heart chambers before dye injection (*A*) but the positive contrast echo appears in its echo free space after injection of the indocyanine green from the left medial cubital vein (*B*) Abbreviations *CW* = chest wall *Pul V* = pulmonary valve *RV* = right ventricle *IVS* = interventricular septum *LA* = left atrium *AML* = anterior mitral leaflet *LV* = left ventricle *LSVC* = left superior vena cava

and echocardiographic findings of 12 patients The DDR of the AML was within normal limits except for patient No 5 who had mitral stenosis The amplitude of the AML and aortic dimension (AOD) were both in the normal range The right ventricle was enlarged in the patients with ASD The left atrial dimension (LAD) was mildly enlarged in patients with mitral stenosis and mitral regurgitation An unusual linear echo was recorded in all patients by M mode echocardiography

Discussion

Recently cross sectional echocardiography has developed in various forms as a mechanical and electronic scanning system [1] These methods have made it possible to demonstrate the anatomical abnormalities and to observe the movement of the heart in real time The high speed mechanical sector scanning system reported previously by our laboratory can also be used to observe t cardiac movement and the anatomical abnorm ities in real time

In general the PLSVC was situated at t posteromedial region to the left atrium a opened to the coronary sinus in the right atriu It was clearly demonstrated in the angiocardi grams as a narrow tubular image and was locat at the left atrioventricular sulcus

Echocardiographic findings of the PLSVC ha not been reported but a few studies on enlarg coronary sinus were presented by other a thors There has also been no documentatio on the cross sectional echocardiographic featur of the PLSVC and the enlarged coronary sinu

In our study a circular echo with an echo fr space and a tubular echo were recorded at th posterosuperior region of the mitral valve in th cross section of the long cardiac axis and th sagittal plane of the chest All of the 12 patien

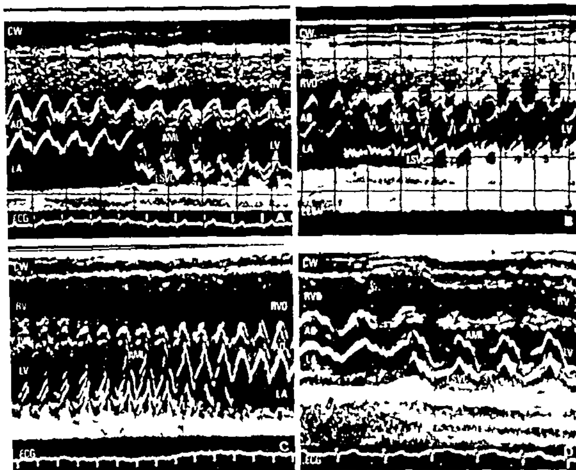

Fig 5 M mode scan echocardiograms in the patients with PLSVC when the transducer was rotated from the aorta to the left ventricle or from the left ventricle to the aorta These pictures were recorded from patients No 1 2 3 and 6 respectively These patients show the abnormal linear echoes posterior to the AML Their movement pattern is slightly changed respectively But these echoes move anteriorly during systole and go back posteriorly in mid diastole An echo free space is recognized posterior to its linear echo Abbreviations *CW* = chest wall *RV* = right ventricle *AO* = aorta *LV* = left ventricle *AML* = anterior mitral leaflet *RVO* = right ventricular outflow tract *LA* = left atrium *LSVC* = left superior vena cava *ECG* = electrocardiogram

anteriorly during systole and retreated posteriorly in diastole Occasionally its movement pattern was similar to that of the AML in some cases It was not considered as an echo of the PML nor as the posterior wall of the left ventricle (LVPW) or that of the left atrium (LVPW) due to the movement and the location Its abnormal linear echo was not detectable in normal subjects and in patients without PLSVC If this echo emanates from the solid tissue the echo free space would not be demonstrable

In the cross sectional echocardiogram through the sagittal plane of the chest a narrow tubular echo was also recognized at the posterior region of the two left sided heart chambers (Fig 6*A*) It was considered to be neither a part of the left ventricle nor the left atrium When the transducer was rotated from the sagittal cross section of the chest to the long cardiac axis it seemed that the circular and tubular echoes emanated from the same lesion

In patient No 2 an injection of indocyanine green was given in the left median cubital vein to confirm the source of the circular echo On the injection of dye the image of the PLSVC was clearly demonstrated as the tubular echo in the sagittal plane of the chest (Fig 6*A*) About one minute after the venous injection the positive contrast echoes appeared in the abnormal cavity (Fig 6*B*) But the upper half was not filled with a cloud of indocyanine green This contrast echo appeared neither in the left ventricle nor in the left atrium

Table I summarizes the clinical hemodynamic

whereas it appeareed neither in the left atrium nor in the left ventricle This abnormal echo was not recognized in normal subjects and other cardiac diseases without PLSVC

In M mode echocardiography, the unusual linear echo was recorded behind the AML It moved anteriorly during systole and went back posteriorly in diastole

Consequently because of the direction of the echo beam the movement and the location of the unusual echo it seems to emanate from the lower part of the PLSVC High speed cross sectional echocardiography has proved to be useful for noninvasive diagnosis of the PLSVC

had the PLSVC opened to the coronary sinus in the right atrium and these abnormal circular and tubular echoes were recognized in all According to the M mode echocardiograms this feature was also shown as an unusual linear echo showing an echo free space posteriorly This is neither the echo of the LVPW nor that of the LAPW since it has an echo free space between the unusual linear echo and more dense structures of the heart wall

It is a matter of controversy as to whether this echo resulting from the enlarged coronary sinus communicates with an anomalous vessel or with the PLSVC itself Gramiak and Sahn[1] reported the echocardiographic findings of the enlarged coronary sinus The same authors recognized an unusual linear echo behind the AML with an echo free space and they stressed that its linear echo moved posteriorly during systole with a resultant narrowing of space followed by a widening in diastole as the margin moved forward In contrast our data showed that the linear echo was gradually enlarged during systole and the anterior margin retreated backward in mid diastole The movement was different in their report and in ours

In this study the transducer was placed at the left side of the sternum in the third or the fourth intercostal space and the echo beam was set to the posteromedial direction perpendicularly through the left atrioventricular sulcus In addition the echo beam went through the left sided margin of the right ventricle and the right ventricle was demonstrated to be a small cavity in the cross section of the long cardiac axis But the right atrium was not recognized in the same cross section On the other hand the right ventricular outflow tract was observed in the cross section of the sagittal plane of the chest but the right atrium and coronary sinus were not recognized However the circular and tubular echoes were clearly recognized posterior to the left sided heart chambers in these cross sections Thus the abnormal echo was considered to emanate from the PLSVC

The positive contrast echo appeared in the abnormal space behind the mitral valve with the injection of indocyanine green from the left median cubital vein But its echo cloud was recognized neither in the left ventricle nor in the left atrium and the circular echo was not considered to derive from the left sided heart chambers It was identified as PLSVC by the movement and the location of the unusual echo and with the contrast echocardiographic technique

The abnormal echoes at the border between the left ventricle and the left atrium and/or in the left atrial chamber should be differentiated from those of PLSVC by echocardiographic examination but they are not always confirmable by M mode echocardiography alone The abnormal echo from these regions was recognized as representing one of the following conditions the posterior mitral leaflet and calcified mitral leaflet in mitral stenosis [11] the diaphragm of the cor triatriatum [1] the mass of the left atrial myxoma [3] the linear or mass echo of the thrombus in the left atrium and thickened chordae tendineae [1] Cross sectional echocardiography served to show a spatial orientation of the heart and these abnormal echoes were clearly observed at the original position Therefore these echoes could be differentiated by this method through their different location movement and characteristics

High speed cross sectional echocardiography has proved useful to the noninvasive diagnosis of the persistent left superior vena cava

Summary

Twelve patients with persistent left superior vena cava (PLSVC) were studied using high speed cross sectional echocardiography with mechanical sector scanning The majority of the examined patients had other associated congenital heart diseases

A circular echo with an echo-free space was demonstrated at the posterosuperior region of the posterior mitral leaflet (PML) in the cross section of the long cardiac axis It was also recognized as a narrow tubular cavity echo posterior to the left atrium and the left ventricle in the cross section of the sagittal plane of the chest This abnormal echo was gradually enlarged during systole and the unusual cavity was largest in early diastole at the E point of the anterior mitral leaflet (AML) and its anterior margin moved back in mid diastole Thus abnormal echo seems to be correspond to the left atrioventricular sulcus By the injection of indocyanine green at the left median cubital vein the positive contrast echo appeared in the cavity which was considered to be PLSVC

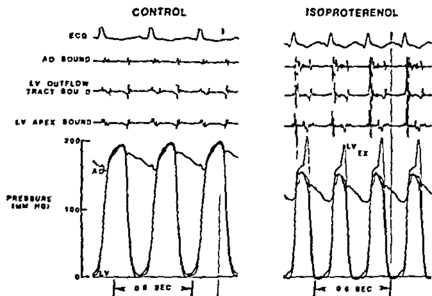

Fig 1 Sound and pressure in the aorta *(AO)* left ventricular *(LV)* outflow tract and LV apex during the control period and during the infusion of isoproterenol During isoproterenol a gradient appeared between the LV apex and outflow tract There was no intraventricular murmur but a murmur did develop distal to the aortic valve

French angiographic catheter tip micromanometer was positioned in the outflow tract of the left ventricle All catheters were made equisensitive

Intracardiac pressure and sound were measured with the same catheter tip transducer as was previously described in detail.[8] Pressure and sound were recorded on an Electronics for Medicine VR 12 photographic recorder at paper speeds of 25 and 250 mm /sec The frequency response of the recording system was flat to 700 Hz with a 3 dB drop at 2100 Hz

A left ventriculogram was obtained with the dog on its left side following the measurement of control pressures and sound Pressures and sound measurements and the ventriculogram were repeated after an intraventricular pressure gradient (> 30 mm Hg) was induced by a constant intravenous infusion of isoproterenol (4 to 8 μg/minute) All ventriculograms were obtained on 35 mm cine film at 60 frames/second

In two dogs intentional entrapment of the tip of the catheter was induced by wedging the catheter in the ventricular trabeculae

Results

Intracardiac measurements of pressure and sound showed no intraventricular pressure gradient or murmurs during the control period The left ventriculogram of all dogs during the control state showed good contraction and no mitral regurgitation

Following the infusion of isoproterenol, an intraventricular pressure gradient that ranged between 47 and 90 mm Hg developed in all dogs No systolic or diastolic murmurs were detected within the left ventricle An ejection murmur was recorded above the aortic valve in all but one dog (Fig 1) The left ventriculogram performed during the infusion of isoproterenol showed almost complete obliteration of the apical region of the left ventricle

In two dogs in which entrapment of the tip of the catheter was induced an intraventricular gradient of 80 mm Hg was observed The left ventriculogram showed a normally contracting left ventricle Recordings of intracardiac sound in both dogs showed no murmurs in the left ventricle or distal to the aortic valve

Discussion

In this study we observed no intraventricular murmur in the obliterating left ventricle despite a prominent intraventricular pressure gradient When a systolic murmur occurred it was distal to the aortic valve These intracardiac sound recordings were strikingly different from those observed in patients with hypertrophic obstructive cardiomyopathy [1, 12] Studies in patients with true ou

Intracardiac phonocardiography in experimental left ventricular cavity obliteration potential clinical applicability for the distinction of obliterating left ventricle from hypertrophic obstructive cardiomyopathy

Hani N Sabbah B S
Mario Marzilli M D *
Paul D Stein M D
Detroit Mich

Left ventricular cavity obliteration may be seen in a spectrum of ventricular disease states[1] It is important to distinguish it from outflow tract obstruction particularly hypertrophic obstructive cardiomyopathy which it may simulate because of differences of treatment The similarity of the clinical features and the hyperdynamic nature of ventricular contractions that are common to both hypertrophic obstructive cardiomyopathy and left ventricular outflow tract obstruction [3] increases the difficulty of differentiation √An intraventricular pressure gradient is generally considered an important diagnostic feature of hypertrophic obstructive cardiomyopathy and other forms of outflow tract obstruction However an intraventricular pressure gradient also occurs in left ventricular cavity obliteration An intraventricular pressure gradient can also appear when the catheter is entrapped in cardiac trabeculae[7]

Because an intraventricular pressure gradient may not actually reflect an outflow tract obstruction it has been suggested that the presence of an intraventricular pressure difference not be accepted as proof of an obstruction without unequivocal proof by other means[1] In view of this other methods for distinguishing between an intraventricular pressure gradient produced by an outflow tract obstruction and a gradient produced by cavity obliteration would be useful We have previously shown that intracardiac sound is useful for identifying subvalvular stenoses and determining the validity of subvalvular pressure *gradients in hypertrophic obstructive cardiomyopathy* subvalvular tunnel stenosis and subvalvular membrane[8] The purpose of this investigation is to describe intracardiac phonocardiography in dogs in which left ventricular cavity obliteration was induced by drugs and to explore the potential use of intracardiac phonocardiography for distinguishing left ventricular cavity obliteration from left ventricular outflow tract obstruction

Methods

Intracardiac pressure and sound were measured in six closed chest mongrel dogs anesthetized with 25 mg/kg intravenous injections of sodium pentobarbital and ventilated with room air A No 6 French catheter tip micromanometer was positioned approximately 1 cm distal to the aortic valve A second No 6 French catheter tip micromanometer was passed retrograde across the aortic valve and positioned as close as possible to the apex of the left ventricle while a No 7

Fig 2 Intracardiac sound aortic *(Ao)* pressure and left ventricular *(LV)* pressure in a patient with hypertrophic obstructive cardiomyopathy *Left* LV catheter was in the apex *Center* LV catheter was within the outflow tract *Right* Both micromanometers were within the aorta The maximal intensity of the murmur occurred within the outflow tract (Reproduced from Henry Ford Hosp Med J 26 35 1978 by permission)

flow tract obstruction (whether due to hypertrophic obstructive cardiomyopathy a subvalvular membrane or a tunnel stenosis) showed that the systolic murmur was of maximal intensity in the outflow tract of the left ventricle distal to the intraventricular obstruction [11, 1] (Fig 2) The subvalvular murmurs were readily detected even when the gradients were small [8, 1]

A pressure gradient measured within the left ventricle may be insufficient to establish a diagnosis of hypertrophic obstructive cardiomyopathy because left ventricular cavity obliteration or catheter entrapment may also cause an intraventricular gradient Therefore additional evidence to support the diagnosis is needed [1] Intracardiac sound may furnish a significant clue to the identification of a true outflow tract obstruction and assist in distinguishing it from cavity obliteration In ventricular cavity obliteration the systolic murmur when present is located distal to the aortic valve and not in the outflow tract of the left ventricle Therefore distinction between true outflow tract obstruction and left ventricular obliteration can be made when simultaneous recordings of intracardiac pressure and sound are made

The murmur generated in dogs with left ventricular cavity obliteration occurred distal to the aortic valve Valvular leaflets act as projections into the stream of flow during systole [3] This results in the breakdown of laminar flow [3] Turbulence distal to the aortic valve would be greatly accentuated in the obliterating ventricle due to the increased blood velocity during ejection [1, 15]

Summary

Intracardiac sound was measured in six dogs four with left ventricular cavity obliteration induced by isoproterenol and two with catheter entrapment In left ventricular cavity obliteration no murmur occurred within the left ventricle Whenever a systolic murmur occurred it was distal to the aortic valve In entrapment no murmur occurred within the left ventricle or distal to the aortic valve Previous studies in patients with hypertrophic obstructive cardiomyopathy showed that the systolic murmur was of greatest intensity within the left ventricular outflow tract Therefore intracardiac phonocardiography may assist in differentiating these conditions which produce an intraventricular pressure gradient

Methods

Animal preparation and instrumentation Eight mongrel dogs weighing from 11 to 30 kg were anesthetized with pentobarbitol 25 mg /kg A 16 gauge 2 inch Teflon catheter (Abbott Cath Abbott Laboratories 4535 16) was inserted percutaneously into the femoral artery and attached directly to a Bell and Howell 4 327 I strain gauge pressure transducer Pressures were recorded on a Hewlett Packard 1064C recorder The frequency response of the total system was flat in terms of amplitude to a frequency of 18 Hz The amplitude began to rise at this point peaked near 35 Hz and fell rapidly for frequencies greater than 35 Hz Heart sounds in a frequency range of 30 to 100 Hz and an ECG were also recorded Duplicate cardiac outputs were measured by the dye dilution method using indocyanine green injected into the central venous circulation while arterial blood was withdrawn through a Gilford cuvette densitometer system Drugs were administered through a short catheter in a foreleg vein

Drug protocol Propranolol was given to limit the heart rate change in response to the vasodilators If initial heart rate was greater than 120 beats/minute propranolol was given to reduce it to 120 beats minute or until 0 5 mg /kg was given If the heart rate was less than 120 beats/minute 0 2 mg kg was given This was done in order to allow a diastolic interval long enough for a sufficient number of points to be sampled for use in the computation routine

The experimental goal during the drug infusions was to infuse a dose that produced a prominent effect on the pressure curve but did not reduce arterial pressure below the physiologic range Sodium nitroprusside (NP) was administered by continuous infusion using a drop counter Prominent effects on the curve shape within the limits of Equation 1 were generally seen with doses of from 2 5 to 10 µg/kg /minute which produced pressure reductions of 20 to 30 mm Hg Nitroglycerin (NTG) was given by continuous infusion on a weight basis Data presented are from dosages of 5 to 10 µg/kg /minute Hydralazine was given by bolus injection in a dose of 1 mg /kg A 30 min period was allowed to reestablish baseline after NP and NTG Hydralazine was given last since its effect is more persistent

Data handling Experimental data consisted of chart recordings of arterial pressures the phonocardiogram and cardiac outputs Data were collected when pressure stabilized on NP after 10 minutes at the particular NTG dose used and 15 minutes after hydralazine injection

Pressure waves were recorded using zero suppression so that pulse pressure covered the full range of the recording scale This reduced the digitization error introduced by the semiautomatic analog to digital conversion done on a Graf Pen (Science Accessories Corporation Southport, Conn) sonic digitizer The digitization system has a resolution of 0 7 mm Hg The output of the sonic digitizer went directly to an IBM 3100 digital computer A sampling rate of 50 samples/sec was used From each set of experimental data three pulses were randomly selected digitized and averaged to form a composite curve that was used by the analysis program The averaging procedure reduced noise levels introduced by the digitization process

The analysis program utilized the portion of the pressure curve occurring after closure of the aortic valve which is interpreted as the transient response of the arterial system to the pressure change occurring in systole This pressure signal was measured at the femoral artery which was considered as point P in Fig 1 The second heart sound (S) was used as a reference in determining the starting point for this transient Watt and Burrus began their analysis at S_2 This however does not take into account pulse wave velocity which must be considered in femoral recordings from dogs particularly when vasodilators are given During these drug infusions we have observed S occurring before the systolic peak in the femoral artery A dicrotic notch remnant on the descending systolic wave was not always visible to serve as a starting point Consequently

Pressure pulse contour analysis in determining the effect of vasodilator drugs on vascular hemodynamic impedance characteristics in dogs

Vasodilator drugs have been shown to be useful in the treatment of heart failure Therapy results in a rise in cardiac output reduction of peripheral resistance and reduction of pulmonary wedge pressure

A primary purpose of vasodilator therapy is improvement in pump function through a decrease in outflow impedance The outflow impedance imposed by the arterial system consists of resistive inertial and compliant components Systemic vascular resistance calculated from mean arterial pressure and cardiac output does not necessarily provide a valid index to absolute impedance or to changes in impedance The impedance function described by Milnor is a frequency domain determination that requires measurement of instantaneous flow and pressure A time domain approach would in theory also be valid and can be determined in a simplified manner by analysis of the pulse wave contour

Watt and associates have utilized an arterial pulse wave contour to analyze vascular properties in man They observed that the diastolic part of the pressure curve can be fit with a high degree of accuracy to the third order equation

$$P(t) = a_1 \exp(-a\,t) + a_3 \exp(-a\,t)\cos(a_5 t + a_6) \quad (1)$$

The a parameters from this equation describe the configuration of the arterial pressure contour in diastole With knowledge of cardiac output this configuration can be further interpreted using the electrical analog model shown in Fig 1 This circuit is a lumped component model of the arterial system It describes gross mechanical behavior considering the pressure wave after aortic valve closure as a decaying transient response The model components C L C and R cannot be equated with any specific vascular anatomy but have physical meaning by analogy R is the peripheral resistance as traditionally defined C and C represent the lumped compliances of the proximal and distal arteries L represents the lumped inertance that is found in the long columns of blood between the proximal and distal vessels of the arterial system Watt and Burrus[3] found that very similar values for the model components were derived from pressure curves measured at various anatomical locations

In the present study we have utilized the basic method of Watt and Burrus[3] to analyze the vascular effects of sodium nitroprusside nitroglycerin and hydralazine given systemically to normal dogs The data reveal that these vasodilator drugs have different effects on the components that make up total vascular impedance

The experimental goal during the drug infusions was to infuse a dose that produced a prominent effect on the pressure curve but did not reduce arterial pressure below the physiologic range Sodium nitroprusside (NP) was administered by continuous infusion using a drop counter Prominent effects on the curve shape within the limits of Equation 1 were generally seen with doses of from 2 5 to 10 μg/kg/minute which produced pressure reductions of 20 to 30 mm Hg Nitroglycerin (NTG) was given by continuous infusion on a weight basis Data presented are from dosages of 5 to 10 μg/kg/minute Hydralazine was given by bolus injection in a dose of 1 mg/kg A 30 min period was allowed to reestablish baseline after NP and NTG Hydralazine was given last since its effect is more persistent

Data handling Experimental data consisted of chart recordings of arterial pressures the phonocardiogram and cardiac outputs Data were collected when pressure stabilized on NP after 10 minutes at the particular NTG dose used and 15 minutes after hydralazine injection

Pressure waves were recorded using zero suppression so that pulse pressure covered the full range of the recording scale This reduced the digitization error introduced by the semiautomatic analog to digital conversion done on a Graf Pen (Science Accessories Corporation Southport Conn) sonic digitizer The digitization system has a resolution of 0 7 mm Hg The output of the sonic digitizer went directly to an IBM 5100 digital computer A sampling rate of 50 samples sec was used From each set of experimental data three pulses were randomly selected digitized and averaged to form a composite curve that was used by the analysis program The averaging procedure reduced noise levels introduced by the digitization process

The analysis program utilized the portion of the pressure curve occurring after closure of the aortic valve which is interpreted as the transient response of the arterial system to the pressure change occurring in systole This pressure signal was measured at the femoral artery which was considered as point P_2 in Fig 1 The second heart sound (S) was used as a reference in determining the starting point for this transient Watt and Burrus began their analysis at S_2 This however does not take into account pulse wave velocity which must be considered in femoral recordings from dogs particularly when vasodilators are given During these drug infusions we have observed S occurring before the systolic peak in the femoral artery A dicrotic notch remnant on the descending systolic wave was not always visible to serve as a starting point Consequently

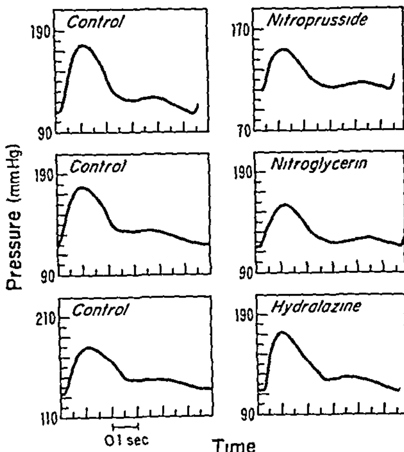

Fig. 2. The effect of vasodilators on the arterial pressure pulse contour. An example from one of the dog experiments reported in this paper is shown.

the time from the end of S_1 to the systolic upstroke was taken as pulse wave transit time. Variations in presystolic ejection time have been considered negligible in comparison to transit time. This transit time was added to the S_2 time to determine the start of pulse wave sampling.

Fitting curves. An iterative curve fitting technique using a Gauss-Newton algorithm was applied (Burrus, personal communication). There are six variables in Equation 1 for which initial guesses are entered. At each iteration the algorithm moves each variable in a direction which reduces the differences between the calculated pressure (from Equation 1) and the actual pressure as measured.

Poor starting guesses for the six variables cause the iteration procedures to diverge. If the change in each a parameter is limited to a part of the calculated correction, the effect of poor initial guesses can be reduced. In practice, step size was limited until the average error was near 3 mm Hg per point. The step size limitation was subsequently removed and the program converged to a minimum value in 2 to 3 additional iterations.

In a few instances when the diastolic wave was broad, the upstroke of the next beat occurred before the pressure at the end point of diastole fell below the pressure minimum between the systolic and diastolic waves. In these cases, the program would not converge unless the pressure curve was extrapolated so that end diastole was below this minimum. The original curves were then fit satisfactorily using the a parameters from the extrapolated curves as initial a guesses. This problem occurred occasionally at high doses of NP and NTG.

Once the a parameters have been determined, it is possible to calculate the time constants RC_1, L/R and RC_2.[7] Peripheral resistance (R) is determined as the ratio of mean arterial pressure to cardiac output. Central venous pressure was considered negligible in this calculation. Model parameters C_1, C_2, and L can then be calculated from the time constants and R. Impedance can be calculated using standard circuit methods.

fits obtainable with Equation 1 indicate that a third-order system can describe the major part of the transient diastolic decay observed in the pressure pulse The transient decay will be determined by characteristics of vessels both proximal and distal to the point of measurement and will depend considerably on the summation of wave reflections in the region of measurement Watt and Burrus[5] found that model components determined from data collected at several different sites along the arterial tree were very similar However it is yet to be determined whether changes in the pulse wave induced by vasodilating drugs are similar at different sampling sites in the arterial tree The model is not meant to be an anatomical model but rather a device to interpret the gross mechanical behavior manifest in pressure measurements

Site of measurement is of consequence in terms of its being proximal or distal. Proximal pressure measurements in man or the dog do not exhibit as prominent a diastolic wave as do distal recordings[11] Bourgeois and associates[1] in fact interpreted the diastolic pressure decay in the thoracic aorta of the dog as a first order system and found its time constant to be proportional to peripheral resistance This would be observed in a Windkessel model with a constant compliance In general curves can be fit to Equation 1 with greater accuracy if the measurement is distal because a diastolic wave is more prominent

Several papers discussed below use frequency domain analysis to evaluate nonresistive components of impedance The use of Fourier analysis to arrive at impedance values as a function of frequency requires few initial assumptions the interpretations of the impedance curves must be based on a particular model Taylor[1] proposed a nonuniform transmission line and then a more elegant model with seventh order branching and nonuniform elasticity In this latter model there is little wave reflection at high frequencies The impedance obtained experimentally at higher frequencies has therefore been interpreted as being representative of the characteristic impedance of the arterial system which depends on its mechanical and geometrical properties The frequency range over which impedance moduli are averaged to obtain a value for characteristic impedance is variable among investigators

Propranolol was given in this study to limit reflex heart rate changes Propranolol does not significantly alter the effects of NP[1] hydralazine[1] or the vasodilatation due to NTG Adams and colleagues[7] measured characteristic impedance in dogs given NP and propranolol although the frequency range they used for this calculation was questionable They did not comment and it was not clear from their results whether propranolol changed the effect of NP on this value We are not aware of studies involving the interaction of propranolol and either NTG or hydralazine with regard to their effects on impedance In the current study propranolol did not completely prevent tachycardia in response to the vasodilating agents This phenomenon has been previously observed[1, 19, 20]

The changes in the a parameters caused by the vasodilators indicate the manner in which they change the pulse contour The significance of these changes may be interpreted using the electrical analog model L (inertance) is determined by properties of blood and the geometry of the vessels and in this case represents effective lumped inertance of a complex geometry Since changes in vessel length and mechanical properties of blood are probably negligible in the present situation a change in L may be assumed to be due to a change in effective mean vascular radius

NTG caused an increase in L, thus suggesting a reduced vascular radius The dominant vascular action of NTG is on the venous bed resulting in decreased venous return to the heart and a fall in cardiac output Since peripheral resistance did not change in the present studies the arterial pressure drop was due to the decreased cardiac output This fall in distending pressure would be expected to passively decrease effective radius and increase L Furthermore Nicolosi and Pieper[3] found that the diameter of the aorta at any given pressure was decreased if venous return was decreased This response could be abolished with alpha blockade or spinal cord transection The reflex sympathetic discharge could be an additional factor in explaining the increase in L noted after NTG Since L is proportional to the inverse of the radius squared a small change in radius could considerably alter L.

The effect of hydralazine is confined to the arterial vascular bed The fall in distending pressure after administration of the drug was due to a decrease in peripheral resistance Inertance was not changed after hydralazine perhaps ...

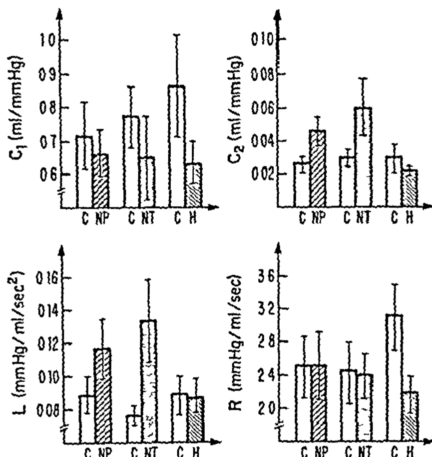

Fig. 3. Variation of circuit parameters for modified Windkessel representation. Data taken from summary in Table I showing mean ± standard error.

frequency domain studies. Clearly, one cannot expect to reproduce impedance functions found from Fourier analysis of pressure and flow signals using a simple lumped parameter model. Impedance moduli determined from our results decreased monotonically with frequency. The reason this occurs in this third order system is explained by Watt and Burrus. The impedance moduli followed the same general patterns for peripheral vascular impedance at the low end of the frequency scale as those discussed in the literature.

Cardiac output fell after NP and NTG while it rose with hydralazine. Modest changes in heart rate occurred despite the use of propranolol.

Discussion

The purpose of this study was to investigate the effect of vasodilator drugs using a simple vascular model whose components are found from pulse contour analysis and knowledge of cardiac output. A stimulus for the study was the observation of pulse contour changes in humans given vasodilators for heart failure and the question of whether pulse contour analysis might be helpful in evaluating clinical response to this therapy. The canine vascular system is not meant to be a model of that system in human heart failure but rather is an experimental tool to determine whether descriptions of the actions of these drugs are consistent with their known effects.

Before discussing the results, a few remarks should be made about this model. The good curve

Table II. The number of dogs which had the indicated change in model components following drug intervention

Component *changes*	Nitroprusside *study*	Nitroglycerin *study*	Hydralazine *study*
Increased C_1	4/8	4/8	1/7
Increased C_2	8/8	8/8	4/7
Increased L	5/8	8/8	2/7
Decreased R	5/8	6/8	7/7

C_1 = proximal compliance; C_2 = distal compliance; L = inertance; R = peripheral resistance.

arterial vasculature was used as a guide in interpreting the observed contour changes The pressure curve during diastole has been viewed as the transient response of the arterial system and can be fit accurately to the equation

$$P(t) = a_1 \exp(-a_2 t) + a_3 \exp(-a_4 t) \cos(a_5 t + a_6)$$

The parameters in this equation and peripheral resistance were used to define the components of the third order Windkessel model consisting of proximal (C_1) and distal (C_2) compliances, an inertance term (L) and peripheral resistance (R) This model describes the gross mechanical behavior seen in the arterial system during diastole The arterial pressure pulse, mean pressure and cardiac output responses to intravenous administration of sodium nitroprusside (NP) nitroglycerin (NTG) and hydralazine (H) were studied using computerized parameter estimating techniques to determine the a_i parameters in the pressure equation and their relationship to the Windkessel components All three drugs caused C to decrease but not significantly NTG increased inertance from 0 076 to 0 134 mm Hg/ml/sec with a p value $< 0\ 05$ NP increased C from 0 027 to 0 046 ml/mm Hg ($p < 0\ 01$) NTG also increased C from 0 030 to 0 060 ml/mm Hg ($p < 0\ 05$) Hydralazine had no significant effect on C but it did reduce R from 3 10 to 2 16 mm Hg/ml/sec ($p < 0\ 01$) Neither NP nor NTG showed a significant decrease in R Thus the three vasodilators apparently have different vascular effects as demonstrated by the pulse contour analysis Such an analysis may be a useful way to evaluate vasodilator therapy

part because it might directly dilate some of the vessels that influence L. Indeed, the drug has been found to localize in the walls of muscular arteries.[24] Proximally, where more elastic tissue is present, radius may be decreased because of less distending pressure and a balance of these effects could lead to a constant L. NP has effects on both venous and arterial vessels, and we observed a nonsignificant increase in L that would be consistent with a summation of the above effects.

Significant changes in proximal arterial compliance were not observed with any of the drugs. According to Bergel's data on the static and dynamic viscoelastic properties of arteries, particularly proximal arteries, compliance should increase when pressure is reduced. In man, Nichols and co-workers found differences in ascending aortic characteristic impedance between two groups of patients with coronary artery disease who had different blood pressures. The group with higher pressure had higher characteristic impedance. In the dog, however, O'Rourke and Taylor[10] did not observe an increase in aortic characteristic impedance when they gave norepinephrine. Cox found that in the dog, characteristic impedance in the thoracic and abdominal aorta, brachial, subclavian, carotid, and femoral arteries was independent of mean pressure in the range of 80 to 150 mm Hg. Cox and Bagshaw perfused the carotid sinus independently and found that ascending aortic characteristic impedance increased when carotid sinus pressure was either increased or decreased from a normalized value, while characteristic impedance in several regional beds varied inversely with changes in carotid sinus perfusion pressure. Since characteristic impedance is determined by both compliance and inertance, a decrease in pressure may have opposite effects on these separate parameters and could therefore result in a variable change in characteristic impedance. In our model, impedance is largely determined by proximal compliance. It seems likely that arterial compliance is the result of various factors superimposed on inherent elasticity and, at least in the dog, it does not appear that changes in pressure have a dominant effect on compliance.

The effect of NP on characteristic impedance in dogs has been studied by Adams and associates and by Bagshaw and colleagues. The calculation of this quantity by Adams and associates may be questionable since it included some low frequencies. Both studies found that characteristic impedance increased in the aorta during NP infusion. In the model used here the impedance seen by the heart at frequencies greater than zero is largely determined by proximal compliance, since it is in parallel with a much larger impedance. This proximal compliance showed an average but nonsignificant decrease with NP. This decrease in C resulted in an increase in the impedance moduli calculated from our model in any frequency range above zero. Therefore these results, using analysis of the pulse wave contour, are compatible with previous studies using Fourier analysis of pressure and flow. We are not aware of any similar studies carried out using NTG or hydralazine with which to compare our results.

In the distal circulation we found that the actions of NP and NTG are different from those of hydralazine. NP has been observed to decrease characteristic impedance in regional beds, an effect which is consistent with the increase in distal compliance in our studies. We did not observe a change in peripheral resistance after NP, a response that is not unexpected in the normal circulation.

Our results imply that NP and NTG reduce distal vessel stiffness, whereas hydralazine increases distal vessel diameter without changing stiffness. We do not have enough information to determine whether these results are due to direct drug actions, are a result of reflex effects on the vascular system, or are due to a combination of these effects.

In human heart failure the arterial system is in a constricted state.[1] This constriction puts a further load on the heart and may lead to a further decrease in cardiac output. Vasodilators interrupt this cycle. It may be helpful when evaluating patients for this therapy to have information about impedance in addition to the other data usually obtained. The technique used in this study is a possible approach to obtain this information. Thus the form of the diastolic wave may provide clinically useful information on the state of the vascular bed. A study to examine vascular parameters in patients with heart failure before and after NP is currently under way.

Summary

The effects of three vasodilators on the shape of the arterial pressure contour in the dog were investigated. A modified Windkessel model of the

Left atrial ball thrombus is a rare disorder. The diagnosis of this serious yet curable lesion has been known to be difficult without cardiac catheterization and angiocardiography.* Although M-mode echocardiography has proven useful in diagnosing left atrial tumors, detection of a ball thrombus in the left atrium is difficult by the conventional technique because of unpredictable motion of the thrombus. Two-dimensional echocardiography allows continuous observation of moving structures with good anatomical orientation in selected cross sections. We report a case of left atrial ball thrombus diagnosed by two-dimensional echocardiography and also describe some of the phonocardiographic and hemodynamic features.

Patient summary

A 55-year-old woman was admitted in January 1976 with a history of recurrent systemic embolization since 1968. She was found to have had a heart murmur in her mid thirties but was asymptomatic until August 1968 when she had an episode of cerebral emboli followed by fatigue and mild dyspnea on exertion. From 1968 to this admission she had at least eight episodes of arterial embolization.

On admission physical examination revealed a heart rate of 65/minute, at times irregular; blood pressure of 140/80 mm Hg; and respiratory rate of 14/minute. The peripheral pulse in her left leg was diminished. The apical impulse was located in the fifth intercostal space at the midclavicular line, and a right ventricular lift was felt at the left sternal border. The first heart sound was accentuated and the second sound was split normally with accentuation of the pulmonic component. An opening snap was present and was followed by rumbling diastolic murmur over the apex. No significant changes in auscultatory findings occurred with alteration of the patient position. The chest was clear to auscultation.

The electrocardiogram revealed atrial fibrillation with mild right ventricular hypertrophy. Chest x-ray examination demonstrated an enlarged left atrium and dilated pulmonary outflow tract with some evidence of pulmonary vascular congestion. The hematocrit was 34.8% and hemoglobin was 11.2 g/100 ml. The erythrocyte sedimentation rate was increased to 89 mm in one hour. The total plasma protein was normal. Protein electrophoresis showed a slight increase in gamma globlin.

Simultaneous recording of the M-mode echocardiogram with phonocardiogram, carotid pulse wave, and electrocardiogram were performed (Fig. 1). The M-mode echocardiogram revealed a reduced early diastolic descent rate of the anterior mitral leaflet with an increased left atrial

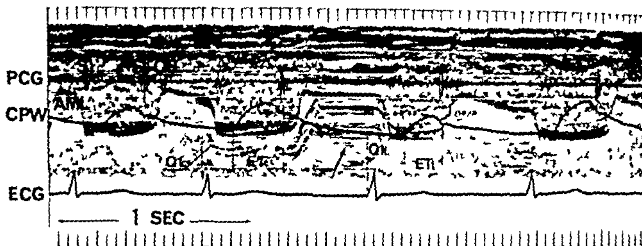

Fig 1 The echocardiogram of the mitral valve with simultaneous electrocardiogram *(ECG)* phonocardiogram *(PCG)* and carotid pulse wave *(CPW)* at a paper speed of 100 mm /sec The diastolic descent rate of the anterior mitral leaflet is abnormally low (30 mm /sec) The tumor echoes are seen *(arrow)* in the second cardiac cycle behind the mitral cusp and disappear quickly at the beginning of ventricular systole An opening snap *(OS)* is noted as the anterior mitral leaflet *(AML)* reaches its maximal anterior excursion The preceding R R interval of the second beat is 710 msec Ql interval *(Qlc)* and ejection time *(ETc)* are 60 msec and 275 msec respectively The third beat has a much longer preceding R R interval (880 msec) However becau e of the mitral orifice obstruction by the tumor disproportionate prolongation of the Ql interval *(Qlt* = 120 msec) and shortening of the ejection time *(ETt* = 200 msec) are noted S = first heart sound S = second heart sound

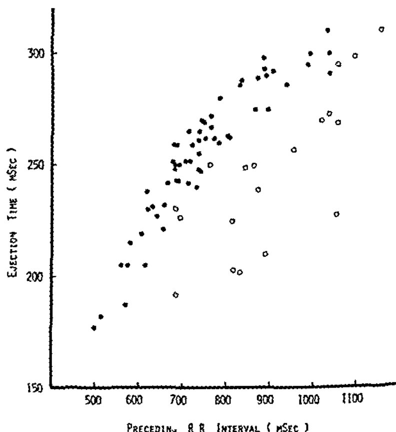

Fig 2 The relatı r between the preceding R R interval and ejection time *Closed circles* represent the ejection time with no precedi tum r echoes in the valve orifice *Open circles* represent the ejection time just after the appearance of the t m r echoes A logarithmic correlation (y = −0.871 + 0 170 ln x r = 0 94 n = 58) is found between the preceding R R interval and the ejection time with no preceding tumor echoes Significant reduction of the ejection time is s n after the appearance of tumor echoes in the valve orifice

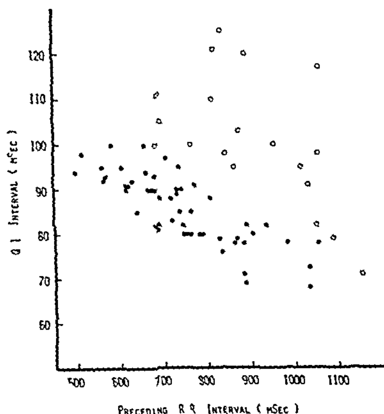

Fig 3 The relation between the preceding R R interval and Q to the first sound interval. *Closed circles* represent the Q to the first sound interval with no preceding tumor echoes *Open circles* represent the Q to the first sound interval after the appearance of tumor echoes. Significant negative correlation (y = 122 – 0 049 x r = 0 80 n = 58) is seen between R R interval and the Q to the first sound interval with no preceding tumor echoes. The Q to the first sound interval is significantly prolonged after the appearance of the tumor echoes in the valve orifice

dimension It also demonstrated tumor echoes *(arrow)* appearing quite sporadically behind the anterior mitral leaflet during diastole and disappearing quickly at the beginning of systole The diastolic descent rate of the mitral valve dropped suddenly from 30 mm /sec to almost zero with the appearance of the tumor echoes in the mitral orifice The phonocardiogram confirmed the presence of the opening snap coincident with the E point of the anterior mitral leaflet An early diastolic plop resulting from abrupt tumor movement [18] was not identified in the beat with tumor echoes A logarithmic correlation was found between the ejection time and the preceding R R interval and Q to the first sound interval was inversely proportional to the preceding R R interval However as can be seen there is a disproportional shortening of the ejection time and a prolongation of Q to the first sound interval in the beat following the appearance of the tumor echoes These findings are summarized in Figs 2 and 3 The apexcardiogram did not show an early systolic notch that was frequently observed in the case of left atrial myxoma [15,18]

The two dimensional echocardiogram was obtained along the long axis of the heart using Aloka SSD 200 (Aloka Co Ltd Japan) Recordings were made with a hand held 60 element 2 25 MHz transducer which provide 200 scanning lines in each cross section at frame rates between 40 to 100/second The effective frame width was 5 cm The multi crystal echocardiography demonstrated (Figs 4 and 5) reduced motion of the mitral cusps and the enlarged left atrium with the essentially normal aortic root and aortic valve leaflets There was a highly mobile spherical tumor in the left atrium without a pedicle attached to the atrial wall The tumor occasionally obstructed the mitral orifice immediately after the opening of the valve and moved back quickly out of the valve orifice into the left atrial cavity at the beginning of ventricular systole

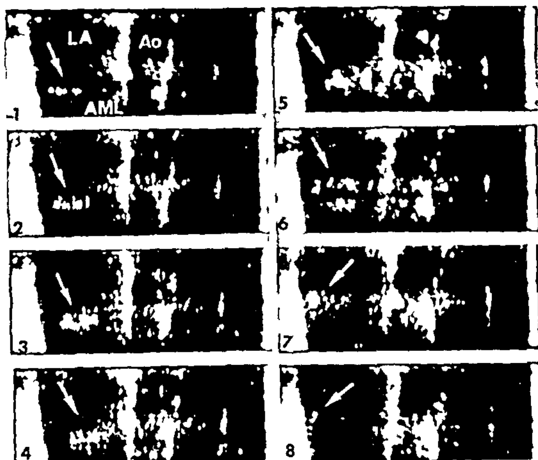

Fig 5 Selected frames (5 cm × 12 cm) from the ultrasonic cross sections obtained along the long axis of the heart (1) (2) Highly mobile pherical tumor (arrow) is seen in the left atrium (LA) measuring 2 cm in diameter There is no pedicle attached to the thrombus The motion of mitral valve is decreased and the LA was enlarged (3) (4) The tumor is approaching to the mitral valve orifice (5) The tumor is obstructing the valve orifice during diastole (6) (7) (8) The tumor moves back quickly to the LA at the beginning of the ventricular systole AML = anterior mitral leaflet Ao = aorta

beat following the appearance of the tumor in the mitral orifice the sudden shortening of the ejection time and the prolongation of Q to the first sound interval were noted Both of these findings are indirect evidence of decreased left ventricular filling associated with an elevated left atrial pressure resulting from the sudden mitral orifice obstruction by the tumor Detailed analysis of the data obtained by the conventional noninvasive techniques could provide critical clues for the diagnosis of the occlusive left atrial tumor

We thank Drs Akira Takeshita and W Lowell Maughan for their valuable comments and discussions in the preparation of this manuscript

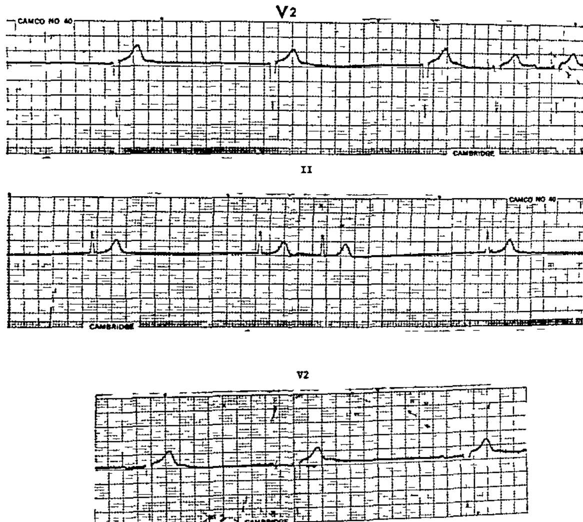

Fig 1B Short rhythm strips from preoperative ECG show junctional rhythm with variable antegrade block occasional sinus capture beats, and a period of profound sinus bradycardia with first-degree AV block

Case report

A 56-year-old white male physician who claimed to be in excellent health his entire life was evaluated medically prior to dental surgery in early January 1978 He denied any cardiac symptoms or signs. Physical examination was normal except for a pulse of 48 beats per minute The patient is a highly trained athlete who for many years has played competitive tennis and has been an avid long-distance runner and cross-country skier His preoperative electrocardiogram (Fig 1) revealed marked sinus bradycardia with a range of 30 to 50 beats per minute An attempt was made to increase the patient's heart rate by vigorous exercise however it rose to only 64 beats per minute A therapeutic trial of atropine 1 mg intravenously increased his heart rate to only 60 beats per minute. The patient underwent 24 hours of Holter electrocardiographic recording and was found to have periods of profound sinus bradycardia as low as 15 beats per minute when asleep as well as occasional sinus pauses and intermittent episodes of junctional rhythm (Figs. 2 and 3) These arrhythmias were felt to be indicative of sick sinus syndrome Although the patient steadfastly denied any symptoms or signs referable to bradycardia it was decided to place a temporary and then permanent transvenous pacemaker

The patient was readmitted to the hospital and monitored overnight during which time his heart rate fell to 11 beats per minute without apparent symptoms (Fig 4) A temporary transvenous pacemaker was inserted via the right femoral vein without difficulty When the tip of the pacing wire reached the right atrium the patient developed asystole lasting approximately 30 seconds A sharp precordial thump restored normal sinus rhythm The pacing wire was then easily advanced across the tricuspid valve and into the apex of the right ventricle without further difficulty Later in the day a permanent pacemaker was installed

Following insertion of the pacemaker the patient noted that he was now more awake and alert during sedentary activities. He then admitted that prior to pacemaker insertion he had been lethargic during periods of rest and inactivity and alert only during active exercise

Discussion

The vast majority of ambulatory active persons with marked sinus bradycardia have typical symptoms of syncope or other obvious evidence of cerebral dysfunction [3] The unique feature of this case is the totally unexpected finding of severe sinus node dysfunction and marked bradycardia

Unusual manifestations of severe sick sinus syndrome

Bruce M Marmor M D F A C P
Martin M Black M D F A C C
Syracuse N Y

The presence of marked sinus bradycardia is usually indicated by symptoms such as dizziness or syncope particularly in active persons Occasionally inactive elderly patients who are asymptomatic are found to have significant sinus node dysfunction with bradycardia on routine electrocardiogram This paper presents a case of an extremely athletic middle aged man who was found to have severe sinus node dysfunction with profound sinus bradycardia and prolonged sinus pauses in the apparent absence of symptoms

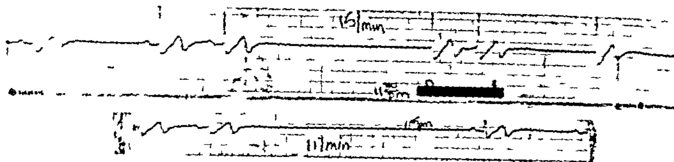

Fig 4 Telemetry strips obtained while the patient was in bed attempting to read a book. *Top strip* shows sinus bradycardia premature atrial beats with capture and sinus arrest terminated by junctional escape beats. *Bottom strip* shows 5½ seconds sinus pause

in a highly trained athlete who denied subtle symptoms until his cardiac function was improved with a pacemaker It appears that he may have been exercising excessively to remain awake and alert through altered autonomic tone We feel, therefore that there is a subgroup of patients with sick sinus syndrome who do not have the typical cerebral symptoms but may rather express a feeling of well being only during active exercise When such symptoms are exhibited we suggest that the patient have ambulatory 24 hour cardiac monitoring in order to demonstrate possible sinus node dysfunction or other bradyarrhythmias

Another important feature of this case was the episode of prolonged sinus arrest occuring when the temporary pacemaker tip reached the right atrium The exact electrophysiological mechanism is unclear however the episode might have been prevented had the patient been given atropine prior to the temporary pacemaker insertion [4] Therefore perhaps patients with severe sick sinus syndrome manifested by markedly prolonged sinus pauses in the range of 4 to 5 seconds should be given a substantial dose of atropine (1 0 to 2 0 ml intravenously) shortly before the insertion of a temporary pacing wire in order to avert prolonged sinus arrest

Summary

An extremely athletic 56-year old male physician was found to have profound sinus bradycardia His only symptom was markedly increased alertness while actively exercising During pacemaker insertion he had an episode of prolonged sinus arrest terminated by a precordial thump This case suggests that exercise can alter autonomic tone and increase cardiac output in sick sinus syndrome causing improvement in possibly unrecognized subtle cerebral symptoms. It also appears that patients with profound sinus bradycardia should be given a substantial dose of atropine prior to pacemaker insertion in an effort to prevent prolonged sinus arrest

malaise fatigue or weight loss Fatigue occurs in nearly all patients and the majority report anorexia and weight loss [5] Constitutional manifestations occasionally are the only findings present and may be attributed by those around the patient to aging or senility Such cases serve as reminders of the need to consider giant cell arteritis in older individuals with failing health Psychosis mental depression and confusion may occur also A low grade fever is frequent and occasionally patients may present as a case of fever of unknown origin

Because of the prominence of these nonspecific symptoms patients sometimes undergo extensive evaluations including exploratory laparotomy to rule out occult malignancy or infection before the presence of giant cell arteritis is realized

Headache is a common initial symptom and is present in up to 90% of patients in some series The headache typically is severe and is localized to the region of the temporal arteries The pain may be constant or intermittent and may be described as boring or lancinating in character However there is such variation in the location and type of pain that giant cell arteritis should be considered in any older patient with a new headache When scalp pain is also present the patient may complain of discomfort combing the hair wearing a hat or laying the head on a pillow

Temporal artery abnormalities are the most helpful physical findings in recognizing giant cell arteritis and are detectable in the majority of patients [3,6] The combination of a tender and swollen or nodular temporal artery in association with other symptoms of arteritis virtually assures the diagnosis (Fig 1) The patient may give a history of recent tender nodules or swelling in the area of the temporal vessels which have resolved by the time the physician is consulted The absence of a pulse in a temporal artery is highly suggestive of arteritis but a subjective difference in the strength of the pulsation between the two sides is generally not a reliable indication of disease

Jaw claudication was felt by Horton [5] to be pathognomonic of temporal arteritis and was associated with involvement of the facial artery It occurs in up to one half to two thirds of patients but its presence may be overlooked if the patient is not specifically questioned about pain or fatigue in the jaw muscles with chewing It must be differentiated from the pain in the temporomandibular joints that develops with a single opening or closing of the mandible A similar type of claudication less commonly occurs in the tongue with chewing or in the muscles of deglutition with repeated swallowing [3]

Polymyalgia rheumatica is defined as aching and stiffness in the neck shoulder girdle and/or hip girdle associated with an elevated erythrocyte sedimentation rate [16,26,27] The pain most commonly is felt in the neck and shoulder girdle but may also be severe in the hip girdle muscles

Review

Giant cell (cranial) arteritis a clinical review

Kent A Huston M D*
Gene G Hunder M D**
Kansas City Mo and Rochester Minn

Giant cell arteritis is a disease of the elderly which when recognized early in its course can be treated effectively with corticosteroids Such treatment results in the relief of symptoms and prevention of blindness or other complications due to occlusion or rupture of involved arteries The term giant cell arteritis has been criticized because giant cells are not found exclusively in this disease and in addition they may be difficult to identify in artery biopsy sections from some patients with typical symptoms Cranial arteritis connotes the most frequent location of the arterial involvement but also has shortcomings because the arteries in the neck and proximal branches of the aortic arch may be affected as well as those of the head Other designations which are used include temporal arteritis granulomatous arteritis polymyalgia arteritica and arteritis of the aged but all also have drawbacks to their usage The first report of the disease was by Hutchinson in 1890[1] who hypothesized that his patient s head pain and inflamed artery was caused by a tight fitting hat That explanation seems humorous today but we cannot yet claim any greater understanding of the etiology The disease was not widely recognized until the classic report of Horton and colleagues in 1932 in which the biopsy findings first were described Since then the clinical spectrum of giant cell arteritis has expanded so that we now recognize its association with polymyalgia rheumatica and include it in the differential diagnosis of headache fever of unknown origin and large vessel arteritis

Epidemiology

Giant cell arteritis is not a rare disorder A recent investigation showed that the prevalence of giant cell arteritis in the population aged 50 years and older was similar to that of ankylosing spondylitis[3] The average annual incidence per 100 000 population aged 50 and older rose from 5 1 in 1950 to 54 to 17 4 in 1970 to 74 probably due to greater recognition of the disease[3] The disease rarely occurs in persons under age 50 years and reaches its greatest incidence in those over age 70[3] In four large series totaling 197 patients 65% were in women[4-7] Giant cell arteritis has been reported mainly in persons of European ancestry but its occurrence in blacks has been noted in several recent case reports[8-10] These observations and several reported instances of familial aggregation suggest that genetic factors may influence its occurrence[3, 7, 11, 12] There is no detectable association between giant cell arteritis and malignancy or other forms of vascular disease[3] Several reported cases have been associated with rheumatoid arthritis but thus far no etiologic association between the two diseases has been established[3, 5, 13-16]

Clinical findings

Tables I and II show the symptoms and findings in a series of 60 patients studied prospectively[6] The *onset* of the illness may be abrupt or insidious A patient may note the rapid development of severe proximal myalgias or headache and swollen temporal arteries[1] But more often the disease begins insidiously with onset of nonspecific *constitutional manifestations* such as

incidental findings in the older age group. Claudication of the upper or less often of the lower extremities and diminished peripheral pulses usually improve with corticosteroid treatment when due to giant cell arteritis. Gangrene of an extremity, ischemic neuropathies and Raynaud's phenomenon are less frequent. An unusually tender carotid or other large artery indicates involvement of that vessel.

Occlusions of large vessels are sometimes found in patients with widespread disease and in some instances aortic rupture and dissection occurs. Aortic valve insufficiency has been reported as a consequence of aortic dissection. Infarctions of the brain and myocardium due to giant cell arteritis have been demonstrated at autopsy in some cases. These complications however are unusual. A recent epidemiologic study showed no increase in occurrence of cardiac disease or stroke in patients with giant cell arteritis over that expected to occur in the general population. Involvement of renal arteries may be found at autopsy and erythrocyte casts may be present in the urine. Renal insufficiency or failure however is rare. Involvement of the aorta and other large vessels is probably much more common than can be detected clinically. In one study medial necrosis of the aorta was found in all five patients with giant cell arteritis coming to autopsy and arteritis was found in 1.7% of 889 consecutive postmortem cases when sections of the temporal arteries and aorta were examined.

Other manifestations of giant cell arteritis which are uncommon but nevertheless of interest are glossitis, recurrent blanching of the tongue, gangrene of the tongue and an altered sense of taste and smell. Scalp necrosis has been reported in a few cases but rarely if ever occurs as a result of temporal artery biopsy.

Laboratory findings

The erythrocyte sedimentation rate is the most helpful laboratory test in the evaluation of giant cell arteritis and is markedly elevated in virtually all patients. For practical purposes the absence of a high erythrocyte sedimentation rate eliminates temporal arteritis from diagnostic consideration although giant cell arteritis has been documented by biopsy in a few patients with a normal or mildly elevated erythrocyte sedimentation rate. A mild normochromic or hypochromic anemia is present in the majority of patients. The hemoglobin concentration is usually in the range of 10 to 12 g/dl but occasionally may be lower. The leukocyte count is usually normal but elevations in the range of 10 000 to 20 000 white cells per mm³ occur in about 40% of patients. The serum protein electrophoresis characteristically reveals an elevated alpha 2 globulin. Liver function tests including glutamic oxalacetic transaminase and alkaline phosphatase levels are elevated in many patients and revert to normal with corticosteroid therapy. Liver biopsies generally are normal or show only mild fatty changes but may show granulomatous hepatitis.

Temporal artery angiography has been used to establish the diagnosis or to identify abnormal segments of the vessel to biopsy. The procedure however is time consuming and may have little advantage over temporal artery biopsy alone. In some cases giant cell arteritis is first recognized by the typical angiographic findings in large vessels showing multiple stenotic areas and occlusions at the end of tapered arterial segments.

The relationship of giant cell arteritis to polymyalgia rheumatica

Whether all patients with polymyalgia rheumatica have the same underlying disease is controversial. Various investigators have found that from 24 to 78% of patients with polymyalgia rheumatica show histologic evidence of vasculitis if their temporal arteries are biopsied. The close association between the two entities has led to speculation that all patients with polymyalgia rheumatica have giant cell arteritis. But this idea has not been universally accepted. The majority of patients with positive biopsies have manifestations of giant cell arteritis other than polymyalgia rheumatica. The crux of the matter is what is the risk of serious vascular complications particularly blindness in patients with pure polymyalgia rheumatica. There is incomplete data to answer this question definitively but the risk of blindness in these patients appears to be relatively small. Many if not most patients with only polymyalgia rheumatica can be satisfactorily treated with non steroidal anti inflammatory drugs or low doses of corticosteroids without ever developing

Characteristically the symptoms disturb sleep and there is an accentuation of soreness and stiffness in the morning Although the patient often describes the discomfort in muscle areas local muscle tenderness is not usually as marked as the pain elicited by movement of the shoulders or hips[7, 8] Other joints particularly the knees and sternoclavicular joints may be swollen[11, 3] Peripheral joint abnormalities when present however are usually mild and transient[11, 1, 3] *Polymyalgia rheumatica occurs in 50% or more of* patients with giant cell arteritis and may be the initial manifestation or may appear for the first time as treatment with corticosteroids is being withdrawn[1] Muscle enzymes electromyograms and muscle biopsies are normal[1, 31] Careful histologic studies have demonstrated inflammatory changes in shoulder synovium capsule bursae and other periarticular structures and joint scanning with technetium pertechnetate has shown increased uptake in the shoulders and other joints[3] These findings suggest that synovitis rather than arteritis or muscle disease is the source of the symptomatology in patients with polymyalgia rheumatica

Visual manifestations are present in 25 to 50% of patients and reflect ischemia of the involved structures[1, 6] Transient visual blurring is not uncommon but by itself may not strongly suggest giant cell arteritis Diplopia occasionally accompanied by ptosis is felt to be secondary to involvement of arteries supplying ocular muscles or cranial nerves but this has not been well studied histologically[6, 6] Partial or complete visual loss is usually permanent but may be preceded by transient blindness[7, 3] The funduscopic picture of ischemic optic neuritis with pallor and swelling of the optic disc often accompanied by small hemorrhages and a few retinal cotton wool patches is seen in the majority of patients with blindness[1] Autopsy studies have demonstrated involvement of the ophthalmic and posterior ciliary arteries in individuals with this ocular complication Less commonly the picture of central retinal artery occlusion is observed and in a few patients central blindness due to infarction of the occipital cortex has been demonstrated[3, 2, 41]

Visual loss is usually associated with clinical abnormalities of the temporal arteries and typically begins abruptly in one eye and progresses over the next few days[39] In individuals with bilateral involvement impairment in the second eye is usually noted a few days or weeks after the initial eye symptoms[39] Blindness rarely develops either as an initial manifestation or after more than one year of disease[4, 4] In one series of 122 patients visual loss was the initial symptom in only two individuals When established the visual deficit rarely improves despite treatment with corticosteroids[47] Even the most encouraging review cited visual improvement with treatment in only 15% of patients[6]

The frequency of blindness reported in patients with giant cell arteritis has decreased since the use of corticosteroids but this may be due at least in part to increased recognition of patients with milder forms of the disease[48] Less commonly reported ocular findings are periorbital edema iritis conjunctivitis and ophthalmomalacia[7, 9] Visual hallucinations and bruits over the orbit may occur and may resolve with corticosteroid treatment[35]

Fig 1 Swelling of both branches of the left superficial temporal artery in a patient with giant cell arteritis Enlargement of a temporal artery to this degree is uncommon From Rodnan G P Mannik M Schumacher H R., Jr eds Primer on the Rheumatic Diseases eighth edition Atlanta The Arthritis Foundation (In press) Reproduced with permission

Large artery involvement is clinically detectable in approximately 10% of patients[3, 50, 51] Bruits are commonly encountered but may be

disease[3] Some biopsies show only intimal proliferation and fragmentation of the internal elastic lamina These milder changes have been termed healed temporal arteritis but may be the only histologic abnormality visible in biopsy specimens from some patients with active disease[3, 11] These latter abnormalities may be differentiated from the normal aging changes of temporal arteries which have been well described in normal and autopsy studies[55, 70]

The most important aspect of the histopathology for the clinician to remember is the occurrence of skip lesions Isolated foci of arteritis have been well documented by serial sections of long segments of involved vessels in 28% of patients[73] In some instances the temporal artery biopsy from one side is normal but the contralateral artery biopsy is positive These findings emphasize the need to obtain a long segment of artery and to examine multiple histologic sections of the specimen If a portion of the vessel is abnormal on clinical examination that segment of course should be biopsied initially If frozen sections from one side are negative in a patient strongly suspected of having arteritis the contralateral temporal artery should be biopsied

The relationship to other forms of vasculitis

There are no clear cut histopathologic differences between giant cell arteritis and Takayasu s disease and there is a considerable overlap in the clinical findings These entities are separated predominantly on the basis of age and epidemiologic differences Takayasu s disease typically occurs in young females and is an arteritis predominately involving large vessels Giant cell arteritis occurs almost exclusively in persons over age 50 and involvement of extracranial large vessels is detected in only a minority of cases Headache and polymyalgia rheumatica are more characteristic of giant cell arteritis and this disease appears to carry a more favorable prognosis Takayasu s arteritis is less responsive to treatment and is sometimes associated with erythema nodosum and hypertension which are not features of giant cell arteritis For these reasons it appears that these are separate entities but a few patients with otherwise typical giant cell arteritis develop large artery involvement and follow a clinical course indistinguishable from Takayasu s disease[2, [illegible]]

Giant cell arteritis is more clearly separated from polyarteritis Though these entities both occur in older individuals the clinical course histopathology, and prognosis are sufficiently different to distinguish between them It should be noted however, that patients with polyarteritis may occasionally have involvement of the temporal arteries[17, 3, 76]

Giant cell granulomatous angiitis of the central nervous system appears to be a separate entity with predominant involvement of the small leptomeningeal and intracerebral arteries and veins The manifestations are severe neurologic changes and the illness is generally progressive and fatal[7]

Diagnosis and treatment

A temporal artery biopsy should be obtained in all patients suspected of having giant cell arteritis including those patients in whom the clinical diagnosis seems certain Although the initial often dramatic improvement with corticosteroids seems to confirm the diagnosis biopsy proof often becomes important later in the course when the clinical picture is blurred because the symptoms are suppressed but the sedimentation rate is above normal and the patient has suffered complications of therapy This is especially true if the physician who is treating the patient is not the one who made the initial diagnosis In these situations subsequent treatment decisions are facilitated if the diagnosis initially was confirmed histologically

Corticosteroid therapy should be instituted when the diagnosis of giant cell arteritis is made In patients in whom the clinical impression of giant cell arteritis is strong prednisone can be started immediately and a temporal artery biopsy can be obtained the following day Small or moderate doses of corticosteroids (10 to 20 mg prednisone per day or equivalent) may alleviate the symptoms within a few days but larger doses are indicated initially to prevent blindness The great majority of patients with giant cell arteritis who lose vision do so before treatment is initiated This in itself speaks strongly for the efficacy of corticosteroids in preventing visual complications The few patients who develop visual loss after starting corticosteroids have usually done so within a few days of starting high doses of corticosteroids or within a few weeks of

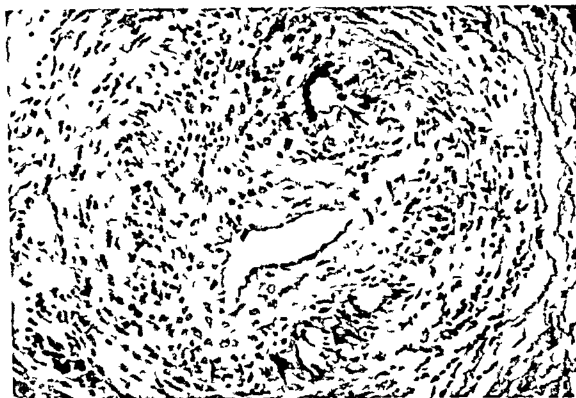

Fig 2 Giant cell arteritis in small branch of temporal artery Multinucleated giant cells *(one pointed out by the arrow)* are present at junction of media and intima There is extensive disruption of all layers of the vessel wall (Hematoxylin and eosin original magnification ×400) From Rodnan G I Mannik M and Schumacher H R Jr eds Primer on the Rheumatic Diseases, eighth edition Atlanta The Arthritis Foundation (In press) Reproduced with permission

vascular complications and with eventual resolution of symptoms The presence of polymyalgia rheumatica alone therefore does not necessitate the use of high dose corticosteroid therapy with its attendant morbidity When steroids are given most patients experience marked relief of symptoms with 5 to 15 mg of prednisone or equivalent per day Even with the use of these low doses of corticosteroids a favorable response is usually so predictable that some authors consider it helpful diagnostically A similar degree of improvement in aching and stiffness may be seen however in patients with rheumatoid arthritis or systemic lupus erythematosus

Whether a patient with polymyalgia rheumatica alone should have a temporal artery biopsy is a decision that needs to be individualized and may be influenced by the severity of the accompanying constitutional symptoms as well as the compliance reliability and general medical condition of the patient The yield of positive temporal artery biopsies is low in patients who after a careful history and physical examination have no other findings suggestive of temporal arteritis Furthermore a negative biopsy does not ensure that a patient will not later develop other manifestations of temporal arteritis Patients treated for polymyalgia rheumatica without a biopsy and those with negative biopsies should be advised to notify their physician if a new headache jaw claudication temporal artery swelling or visual changes develop

Pathology

The characteristic histologic findings of giant cell arteritis are a mononuclear cell inflammatory infiltrate throughout the vessel wall disruption of the internal elastic lamina and the presence of giant cells in the region of the internal elastic lamina (Fig 2) Intimal thickening and thrombosis are additional features The round cell infiltrate in some biopsy specimens may be limited to portions of the wall near the internal elastic lamina Giant cells are not detectable in some cases but their presence or absence does not substantially affect the clinical course of the

starting treatment with doses equivalent to 5 to 20 mg prednisone per day[3,5,17,18] To minimize vascular occlusion or ruptures 40 to 60 mg of prednisone per day or equivalent is recommended for the first month After that if reversible symptoms have cleared and the tests are normal the dose is gradually tapered using the patient s clinical course the erythrocyte sedimentation rate the alpha 2 globulins and hemoglobin levels as guidelines Most patients require lower doses (10 to 20 mg prednisone per day or equivalent) of corticosteroids for several months[3] Patients with extensive large artery involvement may have a worse prognosis and sometimes require treatment with high dose corticosteroids for a longer period of time than one month In one study over one half of patients required treatment for less than a year[3] Corticosteroids can be discontinued in most patients within two years but a few patients require more prolonged treatment usually because of relapses or lingering symptoms such as headache or musculoskeletal pain which become severe when the corticosteroid dose is further reduced[3] Symptomatic relapses usually occur shortly after the corticosteroid dose is reduced or stopped altogether After a patient has remained asymptomatic for one month or longer off corticosteroids further relapses are infrequent[3] Rarely however patients on long term treatment have developed visual loss This possibility makes it necessary to restart or increase the dose of corticosteroids as soon as a relapse is apparent[7,18] Alternate day corticosteroid treatment has been evaluated in a controlled study of giant cell arteritis and is not as effective as daily therapy Persistent symptoms of polymyalgia rheumatica alone may be adequately controlled with aspirin or other nonsteroidal anti inflammatory drugs so that in many instances prednisone may be reduced further or stopped Histologic evidence of giant cell arteritis may persist in arteries examined several years after the onset of disease but this does not appear to be an indication to continue therapy in the absence of clinical evidence of active disease

Long term follow up of unselected patients has shown that giant cell arteritis has no detectable effect on survivorship[3] This favorable prognosis it should be noted is seen with patients who are treated and the survivorship of untreated patients is unknown It is clear that patients sometimes succumb to the complications of the disease but not with a frequency that significantly affects over all survival

Summary

Giant cell arteritis is a disease of the elderly which is more common than previously recognized It is important to be aware of this condition because treatment effectively relieves symptoms and prevents serious complications The disease is suggested when an elderly patient complains of constitutional symptoms headache jaw claudication or the musculoskeletal manifestations of polymyalgia rheumatica Abnormalities in temporal arteries or other cranial arteries or evidence of large vessel involvement may be detected by physical examination A markedly elevated sedimentation rate in association with other clinical features of the disease strongly suggests giant cell arteritis but a biopsy should be performed to confirm the diagnosis Corticosteroid therapy should be started promptly in high doses in order to prevent blindness Prolonged treatment with lower dose corticosteroids is generally necessary for up to 1 to 2 years and sometimes longer for continued symptomatic relief Long term follow up of treated patients has demonstrated no detectable effect on survivorship

Difficult problems in the diagnosis of chest pain

Herbert J Levine M D
Boston Mass

Chest pain is not only a common symptom but one which evokes considerable anxiety among patients and clinicians alike In middle aged or older people a new or recurrent pain in the chest or arm is apt to suggest coronary heart disease and the response of a concerned physician is likely to emphasize this possibility As a general rule however while it is in the patient s best interest to err on the side of overdiagnosis of *acute* coronary heart disease there is good reason not to do so with *chronic* chest pain syndromes Failure to recognize acute coronary heart disease could result in a premature death which might have been prevented in an in patient facility However the risk of sudden death from chronic stable coronary heart disease is relatively low Moreover it is not easily prevented and an erroneous diagnosis could easily evoke unnecessary anxiety and have adverse emotional, domestic, and financial consequences Thus a chronic chest pain syndrome particularly one with atypical features for an ischemic origin should always be met with appropriate skepticism with special attention given to those characteristics or findings which do not fit" the pattern of typical angina pectoris Although no physician wishes to be blamed for overlooking the diagnosis of chronic coronary heart disease one of the more rewarding experiences in medical practice is to be able to replace the cloud of coronary disease with a less serious or sometimes quite benign alternative

The differential diagnosis of coronary heart pain includes a wide variety of non-cardiac conditions disease of the esophagus lungs gall bladder osteoarthritis of the upper spine bursitis of joints disease of the muscles tendons or cartilage of the chest wall etc However it is not sufficient merely to establish that the pain is or is not of cardiac origin or even that it is ischemic heart pain Indeed the prognostic implications and frequently the therapy of ischemic heart pain may be substantially different in the patient with hypertrophic cardiomyopathy angina pectoris with normal coronary arteries (Gorlin Likoff syndrome) mitral valve prolapse aortic stenosis, etc vis a vis the patient whose ischemic pain is due to obstructive coronary artery disease. Although regional myocardial ischemia may be common to all of these an accurate etiologic diagnosis is essential for proper management. In most instances the mimics of coronary heart pain present special features which lead the clinician to question the diagnosis of angina pectoris (Table I) In order to take full advantage of these clues a review of the characteristic features of angina pectoris due to coronary artery disease is essential

Angina pectoris

It is generally believed that the basis for angina pectoris is relative myocardial ischemia. Although a specific nerve stimulant produced by ischemia has not yet been identified it is likely that afferent sympathetic nerve endings are activated by a chemical product of ischemia These afferent sympathetic nerves found in the walls of the coronary vessels and in the myocardium carry impulses to the cervical and upper thoracic sympathetic ganglia and then to the spinal cord via the dorsal roots of the first five thoracic segments [1] Considering the potential variations in nerve traffic across this afferent network, the widely variable expression of ischemic heart pain syndromes is not at all unexpected

nary heart disease but not necessarily to those with acute coronary syndromes Chest pain may last 15 to 20 minutes or more in patients with unstable angina and for hours in the case of frank myocardial infarction

Factors which provoke pain Angina pectoris is generally brought on by physical or emotional stress frequently the combination of the two will provoke pain when either factor alone may not do so Cold weather is a potent factor in evoking angina pectoris by virtue of reflex vasoconstriction of the coronary vessels and as a consequence of the pressor response to cold Isometric hand grip too will provoke angina pectoris in a susceptible individual Indeed the hypertensive and chronotropic response to handgrip probably accounts in large part for the familiar history of angina pectoris developing while a subject carries even a light suitcase at the airline terminal Post prandial angina pectoris is common and occasionally presents as the sole manifestation of ischemic heart pain While the mechanism has been poorly understood recent animal studies suggest that receptors located in the stomach may be responsible for a significant pressor and heart rate response to capsaicin administration Post prandial angina pectoris should be distinguished from abdominal angina While post prandial ischemic pain is the essence of both conditions in the latter ischemic bowel is the source of the pain

According to Gorlin the reproducibility of angina pectoris is surprisingly low in most patients with coronary disease except in subjects with advanced three vessel disease or left main coronary artery obstruction Certainly we are familiar with the first effort phenomenon the individual who experiences angina pectoris on the first fairway of a golf course and then completes the course without pain thereafter Similarly some patients with an unstable form of angina pectoris may develop symptoms with minimal or no provocation—and several weeks later engage in considerable physical exertion without pain with no detectable evidence of an infarction in the interim One very helpful characteristic of angina pectoris is that it is extraordinary for a person suffering from ischemic pain to feel better in the recumbent position The larger cardiac dimensions associated with recumbency increase myocardial oxygen requirements and thus aggravate angina pectoris

Relief of pain Angina pectoris due to coronary artery disease is generally relieved within 1 to 3 minutes by sublingual nitroglycerin Relief following carotid sinus pressure is almost immediate and is dependent upon cardiac slowing[5] Relief of angina pectoris during the Valsalva maneuver occurs during the strain phase (phase 2) of the maneuver and is probably the consequence of a decrease in myocardial wall force (decrease in ventricular pressure and dimensions)[6]

The response of angina pectoris to sublingual nitroglycerin is extremely useful as a diagnostic therapeutic test It should be remembered however that the response must be prompt that is within five minutes and generally less than three minutes Furthermore prompt relief of pain following sublingual nitroglycerin is not diagnostic of angina pectoris Esophageal spasm may be relieved by nitroglycerin and the response to this medication of pain due to spasm of the sphincter of Oddi is often just as dramatic as that of angina pectoris

Physical examination In the absence of congestive heart failure the physical examination is generally not very helpful in confirming the presence of coronary heart disease but it is a crucial procedure in detecting many of the syndromes which masquerade as coronary disease Diastolic filling sounds (S_3 or S_4) are present in less than half of patients with chronic coronary heart disease[7] and thus this finding is of little help in establishing the diagnosis A systolic bulge at or near the apex may be found on palpation and occasionally paradoxical splitting of the S_2 will be detected On the other hand a careful cardiac examination *during* an episode of ischemic heart pain may prove most rewarding A systolic bulge diastolic filling sound paradoxically split S_2 or mitral regurgitant murmur which disappears when the pain subsides is virtually pathognomonic of ischemic heart disease Physical findings suggestive of an underlying metabolic abnormality predisposing to premature atherosclerosis such as skin or tendon xanthomas hypertension diabetic retinopathy etc., are of great importance in the evaluation of patients with chest pain

Electrocardiogram The resting electrocardiogram may be completely normal in as many as 50% of patients with angiographically proven coronary heart disease including those with advanced disease and severe symptoms Of even

In eliciting a history of chest pain five specific characteristics of the discomfort are analyzed type of pain location duration factors causing pain and measures which relieve pain

Type of pain Angina pectoris is commonly described as a pressure sensation a tightness or constricting feeling in the chest Common similes include like a band being tightened around my chest or as if someone were standing on my chest Others will describe it as a burning sensation like indigestion It is rarely described as sharp or knifelike Some patients flatly deny that they have any pain whatsoever Instead they complain of a suffocating feeling or shortness of breath which may be misinterpreted as a symptom of pulmonary disease In the author s experience these anginal equivalents are more commonly encountered among older people and in diabetic subjects

It is particularly helpful to observe the patient while the symptom is being described Frequently the patient will curl the fingers into a clenched fist over the sternum as he speaks a sign attributed to the late Dr Samuel Levine Others may press the sides of the chest inwards with both hands as they search for words to characterize the distress In each instance the character of the discomfort varies little with recurrent episodes

Location of pain Most commonly the pain is felt in the center of the chest under the sternum It may be slightly to the left or less often to the right of center Frequently it will radiate to one or both arms particularly the left and more often down the inner rather than the outer surface to *the elbows wrists or occasionally to the fingers* There may be no true arm pain but instead the arms may be described as feeling heavy or numb Not uncommonly the pain will extend into the throat mandible or even the maxilla In other individuals the pain is in the epigastrium or radiates to the back between the scapulae In some extra thoracic pain (i.e arm or jaw) may exist with no chest discomfort whatsoever

The location of angina pectoris varies greatly from one person to another but generally little if at all with recurrent episodes in a given individual Thus a person who complains of chest pain in varying locations on different occasions is not likely to have angina pectoris Another helpful characteristic is that angina pectoris is not well localized If the painful area can be covered with one finger it probably does not represent ischemic heart pain

Duration of pain Patients with chronic angina pectoris due to coronary artery disease generally obtain relief of their pain within 1 to 5 minutes of rest Pain which lasts only several seconds or is fleeting is never due to coronary heart disease Similarly constant pain lasting days or weeks at a time can safely be assumed to be non cardiac in origin It must be emphasized however that these limits apply to patients with *chronic* coro

suggest mitral valve prolapse as a possible etiology, particularly if the resting electrocardiogram reveals no evidence of a conduction abnormality. Chronic fatigue, anxiety, depression, hyperventilation and a variety of symptoms suggesting a neuropsychiatric origin are common in persons with mitral valve prolapse. On the other hand, aside from appropriate concern for their symptoms, the patient with coronary heart disease and *angina pectoris* who has good ventricular function generally feels quite well between episodes of ischemic pain.

Physical examination. When auscultation reveals a typical mid systolic click late systolic murmur, the diagnosis of mitral valve prolapse is easily established. However, the auscultatory findings in this syndrome may be extremely subtle, evanescent, and in some individuals totally *unrevealing even on repeated examinations* ("silent" mitral valve prolapse). Not uncommonly, careful asucultation in the recumbent and standing position is repeatedly negative while subsequently an unmistakable mid systolic click may appear quite inexplicably. If the clinical syndrome is strongly suggestive of mitral valve prolapse, the diagnosis should never be excluded on the basis of one or two negative auscultatory examinations.

Electrocardiogram. Abnormalities of the resting ECG in mitral valve prolapse may be indistinguishable from those observed in either acute or chronic coronary heart disease. When present, the changes most commonly consist of ST segment depression and/or T wave flattening or inversion, particularly in the inferior leads but also in the lateral or right precordial leads.[12] Characteristically, the extent of the repolarization abnormalities may vary considerably, particularly when associated changes in heart rate are observed. The ST-T wave changes of mitral valve prolapse frequently can be differentiated from those of chronic coronary heart disease by their response to a single dose of propranolol.[1] While repolarization changes due to chronic coronary disease change little 1 to 2 hours following a 40 mg tablet of propranolol, the changes due to mitral valve prolapse often are diminished or may disappear. While this response is not specific for mitral valve prolapse,[1, 13] in the proper clinical setting it may be of great help in distinguishing mitral valve prolapse from coronary heart disease.

Other tests. The exercise ECG may reveal a characteristic "ischemic" response particularly in subjects with some repolarization abnormalities on the resting ECG. While a negative exercise myocardial perfusion scan is helpful in excluding significant underlying coronary heart disease, a positive test has been reported in some patients with mitral valve prolapse and normal coronary arteriograms.[16]

Summary. Mitral valve prolapse should be suspected in any patient with atypical chest pain, particularly in a female without important risk factors for atherosclerotic disease. Associated symptoms of palpitations, lightheadedness, syncope, or conspicuous functional symptoms should immediately alert the physician to this diagnosis, and the presence of repolarization abnormalities on the resting and/or exercise ECG should not be *interpreted necessarily as favoring* a diagnosis of coronary heart disease. Repeated auscultatory examinations in the supine, standing, and squatting positions may be necessary to detect the non ejection click or, when present, the dynamic mid late systolic murmur. It should be remembered that there is at present no "gold standard" for establishing this diagnosis, and convincing auscultatory findings should not be "over ruled" by a negative echocardiogram or left ventriculogram.

Hypertrophic cardiomyopathy. Hypertrophic cardiomyopathy (HCM) frequently may masquerade as chronic coronary heart disease, particularly when the dominant symptom is angina pectoris. When HCM is associated with *left ventricular* outflow tract obstruction, a prominent ejection or regurgitant systolic murmur *will alert* the physician to consider a number of conditions other than uncomplicated coronary heart disease. However, the diagnosis of HCM may be especially difficult when little or no outflow tract obstruction is present and the cardiac examination may reveal few clues to the correct diagnosis. While ischemic heart pain due to inappropriate (or appropriate) hypertrophy of the left ventricle is generally indistinguishable from that due to obstructive coronary disease, often there are useful clues which suggest the former process.

Description of pain. Although angina pectoris is a common symptom of HCM, it is reported to be the initial symptom in as few as 10% of symptomatic patients.[17] In the obstructive form

greater importance is the observation that *during* chest pain ST segment depression is only found in approximately half of patients suffering angina pectoris at rest[4] Thus a normal resting electro cardiogram (random or during pain) is not particularly helpful in the differential diagnosis of ischemic heart pain

Stress testing The exercise electrocardiogram has proved extremely useful in the detection of symptomatic coronary heart disease particularly in males However the ability of this test to confirm or exclude coronary heart disease is greatly influenced by the prevalence of this disease in the population under study For example in a recent large multicenter study it was found that a positive stress test increased the likelihood of coronary disease by only 6 to 20% and a negative test decreased the likelihood by only 2 to 28% if the pre test prevalence was estimated on the basis of sex and a description of the chest pain syndrome Expressed differently when the prevalence of coronary disease in high—i e among males with classic angina pectoris—a positive test is highly predictive of coronary heart disease whereas in a group of females with atypical symptoms a negative test is highly predictive of no coronary disease and a positive test would correlate poorly with the presence of coronary disease When exercise electrocardiography is coupled with either myocardial perfusion scanning or radionuclide cineangiography the sensitivity and specificity of stress testing are greatly enhanced

Mimics of coronary heart pain

Chest pain syndromes that masquerade as coronary heart disease generally present one or more characteristics which distinguish them from typical angina pectoris The atypical feature may be a subtle but unmistakable violation in the classic description of Heberden s angina A convincing pain syndrome may come under suspicion because of its rare association with syncope or paroxysmal rapid heart action The electrocardiogram may be inappropriate or the patient s posture may suggest a spinal origin of the symptoms In any case the physician should be particularly alert to unusual aspects of the history or any unexpected findings Among the many conditions that mimic coronary heart pain a number are particularly common offenders

Mitral valve prolapse In some instances the chest pain syndrome associated with mitral valve prolapse may be indistinguishable from that observed in subjects with coronary artery disease that is a typical effort syndrome with all or most of the features of classical angina pectoris More often however there are atypical features which alert the physician to a diagnosis other than coronary heart disease

Description of pain Rest pain is not uncommon The duration of pain frequently is variable—at times consistent with classical angina pectoris while at other times lasting for hours at a time Unlike the situation in the patient with chronic coronary heart disease the location and radiation of the pain may vary in some patients with mitral valve prolapse during recurrent episodes of pain The response to nitrates often is unpredictable—even in the same individual generally prompt relief of pain is not observed following sublingual nitroglycerin In the author s experience subjects with mitral valve prolapse often feel better in the recumbent position when they are having chest pain—a characteristic rarely observed in patients with coronary heart disease This observation is not unexpected when one considers that the relative cardiac dilatation which accompanies recumbency increases wall tension and thus myocardial oxygen requirements aggravating regional ischemia due to coronary disease Mitral valve prolapse on the other hand is reduced as ventricular dimensions are increased and thus recumbency predictably would lessen the mechanical abnormality of prolapse Subjects with mitral valve prolapse who have an effort syndrome suggestive of angina pectoris frequently describe spontaneous variations in the severity of the symptoms that are unrelated to the level of activity They may be relatively free from pain for weeks or months only to experience recurrent bouts of chest pain with relatively little provocation

Associated symptoms While patients with chronic coronary disease and angina pectoris may be subject to ventricular ectopy or paroxysmal rapid heart action palpitations are not generally associated with classic angina pectoris In contrast palpitations are a prominent feature of mitral valve prolapse and commonly coexist with periods of chest pain Certainly recurrent light headedness or particularly syncope in a person with a chest pain syndrome argues against coronary disease as the cause and should immediately

HCM than to any other condition Q waves in the ECG simulating myocardial infarction may be present in the anteroseptal or inferior leads and have been reported in up to half of patients with HCM[18]

Summary In advanced, but as yet unsuspected cases of obstructive HCM the ejection or regurgitant systolic murmur generally leads the physician to consider a valvular lesion which when subsequently evaluated by echocardiography is correctly identified as being due to HCM However in symptomatic individuals with no murmurs or an innocent systolic murmur careful attention to inappropriate findings in the history physical examination and ECG is necessary to distinguish the patient with HCM from one with coronary heart disease Conspicuous dyspnea symptoms of cerebral ischemia, evidence of left ventricular hypertrophy on the ECG and physical examination (particularly in the absence of radiographic evidence of cardiomegaly) an 'inappropriate ECG the absence of risk factors for atherosclerosis—all should suggest the possibility of early HCM in the patient complaining of ischemic heart pain

Esophageal syndromes Esophageal pain is frequently misdiagnosed as ischemic heart disease although the description of pain is rarely that of typical angina pectoris However, there are clinical features shared by both diseases which may seriously confound the diagnosis

Description of pain The common terms used to describe the pain of esophagitis are heartburn warmth fullness pressure distress gnawing a lump—terms quite indistinguishable from those used to describe angina pectoris Among these perhaps the most common is *heartburn* or its *equivalent When this term is used it is helpful* to ask whether the burning sensation more closely resembles *heat* or *acid* The latter response is quite characteristic of esophagitis but is almost never used to describe ischemic heart pain Symptoms of esophagitis generally occur after eating and are often initiated or aggravated by recumbency While this sequence is not particularly common in patients with angina pectoris is it important to remember that with rare exceptions patients with ischemic heart pain too avoid lying flat when they have pain

The distribution of esophageal pain is quite similar to that of angina pectoris Most often it is midline thoracic or abdominal (from the suprasternal notch to the epigastrium) but may extend to the left or right chest the shoulders, arms and hands, the back or throat In one series of ninety six patients discomfort was substernal in 70 per cent abdominal in 67 per cent and radiated to the neck, arms or back in 19 per cent of patients[19] Although exertional pain has been *reported in some patients with esophagitis*[20] the possibility of coexisting coronary heart disease in these patients has not been completely excluded

Esophageal pain simulating ischemic heart pain may also be the consequence of diffuse esophageal spasm or less often achalasia In a group of 43 patients with chest pain and either normal coronary angiograms or negative exercise tolerance tests esophageal manometrics revealed high amplitude non peristaltic contractions in one third of the patients[2] Diffuse esophageal spasm is generally initiated by swallowing particularly of cold liquids, and increased sensitivity to cholinergic drugs and endogenous gastrin may play a role in precipitating symptoms[21] A favorable response to nitrates in subjects with diffuse esophageal spasm further confounds the problem of distinguishing this condition from angina pectoris[4, 5]

Summary Since both esophagitis and coronary heart disease are common conditions, it is expected that the two diseases will frequently coexist Indeed the demonstration that one or both conditions are present does not establish with certainty the cause of a given pain syndrome While endoscopy may indicate that esophagitis is present a positive esophageal acid perfusion test provides further evidence that *esophageal erosion is the source of pain*[19] Similarly chest pain and dysphagia precipitated by swallowing cold liquids and associated with high amplitude non peristaltic esophageal contractions strongly suggest that diffuse esophageal spasm is responsible for the symptoms[21] In the presence of both coronary and esophageal disease provocative tests may be necessary to ascertain the origin of an atypical chest pain syndrome

Radicular syndromes The pain of spinal particularly cervical root compression does not frequently mimic ischemic heart pain Nontheless, in some instances an effort syndrome virtually indistinguishable from angina pectoris may be

of the disease the most common symptom is dyspnea and in one report this proved to be in the initial symptom in 60% of patients [17] Certainly patients with chronic coronary heart disease and angina pectoris may also complain of dyspnea but it is unusual for this symptom to precede the onset of ischemic pain unless it were misinterpreted as an anginal equivalent Thus a careful search for HCM should be made in any individual with angina pectoris who has coexisting or antecedent dyspnea which is not easily explained by transmural infarction cardiomegaly or either regional or diffuse hypokinesis of the ventricle

While the character duration and radiation of ischemic heart pain in HCM and chronic coronary heart disease are quite the same the factors associated with the inception and termination of pain in some instances may be different For example it has been reported that the Valsalva maneuver may effect prompt relief of angina pectoris in subjects with coronary heart disease [6] Since relief of pain occurs during the strain phase of the maneuver it was presumed that a decrease in wall force (decreased ventricular pressure and dimensions) and thus myocardial oxygen requirements was responsible for this phenomenon However in a subject with obstructive HCM outflow tract obstruction is provoked by the Valsalva maneuver and thus the procedure may have quite the opposite effect Occasionally patients with obstructive HCM find that they can obtain relief of their ischemic pain by squatting—a maneuver which increases ventricular dimensions and hence lessens outflow tract obstruction While subjects with HCM often find nitroglycerin useful in terminating episodes of angina an adverse response to nitrates may be observed in those with dynamic outflow obstruction In this circumstance the reduction in ventricular preload brought about by nitrates may precipitate ischemic pain or may evoke symptoms of cardiogenic cerebral ischemia

Associated symptoms As in the case of mitral valve prolapse the association of chest pain with lightheadedness dizziness or syncope should always arouse one s suspicion of HCM Unlike mitral valve prolapse however the chest pain is generally ischemic in character and the symptoms of cerebral ischemia are more apt to be effort related Both atrial and ventricular arrhythmias are common in HCM the latter not infrequently present early in the disease and occasionally the first manifestation of HCM may be a fatal ventricular tachyarrhythmia during strenuous physical exertion Atrial fibrillation tends to be a late complication of HCM and is generally poorly tolerated by the non compliant hypertrophied ventricle

Physical examination The patient with typical ischemic heart pain and a dynamic systolic murmur which is increased in the upright position or during the Valsalva maneuver and which softens during squatting is generally easily identified as having obstructive HCM The real diagnostic challenge is to identify the patient with HCM who has little or no outflow tract obstruction In some such patients no murmur is heard in the supine position but a systolic murmur can be elicited by the appropriate provocative maneuvers In others the only suspicious finding may be a brisk arterial pulse an abnormal left ventricular impulse or an unusually prominent fourth heart sound which frequently may be felt as well as heard

Electrocardiogram Although the ECG was found to be abnormal in all 64 patients with obstructive HCM reported by Braunwald and colleagues [17] in 1964 a normal ECG is not uncommon in patients with mild HCM particularly those with no outflow tract obstruction or those examined early in the course of their disease Generally however the tracing is abnormal most commonly revealing varying degrees of left ventricular hypertrophy intraventricular conduction abnormalities or non specific repolarization changes However much more useful in the evaluation of patients with angina pectoris are those abnormalities which don t quite fit the diagnosis of coronary heart disease For example broad and/or tall P waves suggestive of atrial enlargement are common in HCM and unusual in patients with coronary heart disease A slurred inscription of the R wave (delta wave) with or without a short P R or prolonged QRS interval favors a diagnosis of HCM and this finding too is relatively less common in patients with coronary disease Indeed the ECG in HCM often is best described merely as bizarre

Although electrocardiographic evidence of old transmural myocardial infarction is a hallmark of coronary heart disease this finding in an asymptomatic young individual is more apt to be due to

HCM than to any other condition Q waves in the ECG simulating myocardial infarction may be present in the anteroseptal or inferior leads and have been reported in up to half of patients with HCM [18]

Summary In advanced, but as yet unsuspected cases of obstructive HCM the ejection or regurgitant systolic murmur generally leads the physician to consider a valvular lesion which when subsequently evaluated by echocardiography is correctly identified as being due to HCM However in symptomatic individuals with no murmurs or an innocent systolic murmur careful attention to inappropriate findings in the history physical examination and ECG is necessary to distinguish the patient with HCM from one with coronary heart disease Conspicuous dyspnea symptoms of cerebral ischemia evidence of left ventricular hypertrophy on the ECG and physical examination (particularly in the absence of radiographic evidence of cardiomegaly) an inappropriate ECG the absence of risk factors for atherosclerosis—all should suggest the possibility of early HCM in the patient complaining of ischemic heart pain

Esophageal syndromes Esophageal pain is frequently misdiagnosed as ischemic heart disease although the description of pain is rarely that of typical angina pectoris However there are clinical features shared by both diseases which may seriously confound the diagnosis

Description of pain The common terms used to describe the pain of esophagitis are heartburn warmth fullness pressure distress gnawing a lump—terms quite indistinguishable from those used to describe angina pectoris Among these perhaps the most common is *heartburn* or its equivalent When this term is used it is helpful to ask whether the burning sensation more closely resembles *heat* or *acid* The latter response is quite characteristic of esophagitis but is almost never used to describe ischemic heart pain Symptoms of esophagitis generally occur after eating and are often initiated or aggravated by recumbency While this sequence is not particularly common in patients with angina pectoris is it important to remember that with rare exceptions patients with ischemic heart pain too avoid lying flat when they have pain

The distribution of esophageal pain is quite similar to that of angina pectoris Most often it is midline thoracic or abdominal (from the suprasternal notch to the epigastrium) but may extend to the left or right chest the shoulders, arms and hands the back or throat In one series of ninety six patients discomfort was substernal in 70 per cent, abdominal in 67 per cent and radiated to the neck arms or back in 19 per cent of patients [19] Although exertional pain has been reported in some patients with esophagitis,[20,21] the possibility of coexisting coronary heart disease in these patients has not been completely excluded

Esophageal pain simulating ischemic heart pain may also be the consequence of diffuse esophageal spasm or less often achalasia In a group of 43 patients with chest pain and either normal coronary angiograms or negative exercise tolerance tests esophageal manometrics revealed high amplitude non peristaltic contractions in one third of the patients [22] Diffuse esophageal spasm is generally initiated by swallowing particularly of cold liquids and increased sensitivity to cholinergic drugs and endogenous gastrin may play a role in precipitating symptoms [23] A favorable response to nitrates in subjects with diffuse esophageal spasm further confounds the problem of distinguishing this condition from angina pectoris [24, 25]

Summary Since both esophagitis and coronary heart disease are common conditions it is expected that the two diseases will frequently coexist Indeed the demonstration that one or both conditions are present does not establish with certainty the cause of a given pain syndrome While endoscopy may indicate that esophagitis is present a positive esophageal acid perfusion test provides further evidence that esophageal erosion is the source of pain [19] Similarly chest pain and dysphagia precipitated by swallowing cold liquids and associated with high amplitude non peristaltic esophageal contractions strongly suggest that diffuse esophageal spasm is responsible for the symptoms [22] In the presence of both coronary and esophageal disease provocative tests may be necessary to ascertain the origin of an atypical chest pain syndrome

Radicular syndromes The pain of spinal particularly cervical root compression does not frequently mimic ischemic heart pain Nontheless in some instances an effort syndrome virtually indistinguishable from angina pectoris may b

due to thoracic or lower cervical nerve root compression Generally however historical features or provocative maneuvers on physical examination will lead to a correct diagnosis

Description of pain *Dorsal* root pain is generally sharp and piercing often of lightning character and may be associated with superficial paresthesias On the other hand *ventral* root pain may be a deep boring dull discomfort simulating ischemic heart pain Spinal pain may occur over any part of the chest the paraspinal area the axilla or shoulder girdle and may radiate down the inner or outer aspect of the arm to the fingers Generally it is bilateral but the symptoms from one side of the body most often dominate

The three major characteristics of root pain are (1) pain with movement of the body (2) pain on coughing sneezing etc (Déjerine s sign) and (3) pain after prolonged recumbency[26] Shoulder or arm pain may be brought on by rotation of the head to the involved side or flexion of the head to the uninvolved side Chest pain is often precipitated by bending hyperextension of the upper spine or by throwing back the shoulders Déjerine s sign is most apt to be observed when the condition is acute Indeed the onset of symptoms may be traced for example to a particularly vigorous sneeze The development of root pain after several hours in bed is a common feature of this syndrome and thus may be misinterpreted as nocturnal angina particularly when associated with other constitutional symptoms (vide infra)

Repeated jarring such as occurs with running jogging driving on a bumpy road jumping rope etc will often provoke root pain and thus exhibit characteristics which may closely resemble angina pectoris Recently a syndrome designated cervicoprecordial angina has been described which consists of substernal chest pain simulating angina pectoris but due to cervical root compression[27] Exercise induced pain was present in 14 of 17 patients and 12 obtained prompt relief of symptoms with nitroglycerin Chest pain was reproduced by a number of provocative maneuvers (vide infra) and all patients had normal coronary arteriograms The pain was substernal radiating to the arms and fingers in most patients and usually lasted less than 15 minutes Relief of symptoms was obtained in the majority of patients by using cervical traction and a six week course of phenylbutazone although in some patients laminectomy and foraminotomy were necessary for successful treatment

Associated symptoms Paresthesias are common and occasionally precede the onset of root pain Tingling numbness and stiffness particularly of the fingers are generally aggravated by the same maneuvers which provoke pain Vertigo is not infrequently associated with upper cervical root compression and may be accompanied by nausea Difficulty in breathing without hyperpnea has been reported in one third of patients with chest pain due to cervical root compression[26] further suggesting a cardiac origin of these symptoms In rare instances this peculiar respiratory distress may be the only manifestation of the disease

Physical examination The diagnosis of spinal root compression is established by a series of provocative maneuvers Stretching the arm across the chest while pulling the head toward the flexed shoulder and inhaling deeply is one such maneuver Pressure applied to the top of the head with the head tilted slightly to one side or the other (Spurling s compression maneuver) is another Tenderness to deep palpation is an extremely valuable sign In Davis series[6] of 100 patients with chest pain of root origin moderate or marked spinal tenderness was present in 94% and parasternal or axillary tenderness was present in 98% of those with thoracic root compression[2] In one third of patients firm pressure over the spinous processes evoked referred pain over the anterior or lateral chest wall Hyperesthesia or hypesthesia to pin prick or light touch may be present Maneuvers used to identify the thoracic outlet syndromes are also important the Adson maneuver for the scalenus anticus syndrome (obliteration of the arterial pulse during inspiration while the chin is elevated and rotated to the affected side) the chicken ready to fly sign (abduction and rotation of the upper arms) for the costoclavicular syndrome and the hyperabduction maneuver for the pectoralis minor and humeral head syndromes.

Summary Chest pain produced by spinal root compression may on occasion be deep boring constricting short lived evoked by physical exercise and relieved by rest and even nitroglycerin Since symptoms of vertigo nausea and respiratory distress may accompany radicular pain distinction between spinal root pain and angina

tension are not infrequent during episodes of variant angina. The underlying mechanism responsible for this clinical syndrome is coronary artery spasm. Nonetheless, the majority of patients with variant angina also have fixed coronary arterial lesions with a high incidence of single vessel disease. Despite generally good exercise tolerance, an abnormal exercise ECG is not unusual in patients with variant angina[37] and thus it is of limited value in distinguishing typical and variant angina. Nitrates are extremely effective in relieving ischemic pain due to coronary spasm. On the other hand, beta adrenergic blocking agents may aggravate symptoms. Hence a paradoxical response to propranolol therapy should alert the physician to consider the diagnosis of variant angina.

Chest wall syndromes. Chest pain of musculoskeletal origin is often dull and aching but at times may be sharp or stabbing, particularly when the involved portion of the thorax is moved. Regardless, the character of the pain may be embellished by fear of a cardiac origin giving rise to hyperventilation, palpitations, or a visceral discomfort superimposed upon the primary musculoskeletal pain. With rare exceptions the diagnosis is easily established by a careful physical examination. Tietze's syndrome, for example, is an uncommon condition consisting of painful, tender, and swollen costochondral or sternoclavicular junctions sometimes initiated by excessive strain on the rib cage.[3] The upper ribs are most commonly affected, and pain is frequently aggravated by respiratory straining, weather changes, and perhaps by anxiety. Since physical activity may trigger chest wall pain, the symptoms may be misinterpreted as angina pectoris. Although the course may be prolonged, symptoms are generally easily controlled by reassurance, heat, salicylates, or if necessary by local injections of xylocaine or steroids. Costochondrodynia is far more common than Tietze's syndrome and differs in that there is no swelling of the involved, tender costochondral junction. In these and most other painful chest wall syndromes, the key to the diagnosis is localized tenderness in the painful area or referred chest pain with localized pressure to a portion of the chest wall.[3]

Pericarditis. Ordinarily there is little difficulty distinguishing the pain of pericarditis from that of myocardial ischemia. The pleuritic component is identified by deep breathing, sniffing, or by any abrupt motion of the diaphragm or pleural surface. Rarely, however, acute pericarditis will present with an oppressive, steady chest pain and constitutional symptoms identical to that of patients with myocardial ischemia or infarction. Serum elevations of creatine kinase MB isoenzyme and acute repolarization changes on the electrocardiogram may mislead the physician to favor a diagnosis of infarction. Careful attention to antecedent symptoms of a viral infection, inappropriate fever, failure of the elevated ST segments to evolve a pattern of transmural or non transmural infarction, a negative "hot spot" scan, etc., may be necessary to establish that the process is one of epicardial injury rather than coronary vascular disease. Repeated auscultation for a pericardial friction rub and an echocardiographic search for pericardial fluid will help to resolve the issue.

There are many other medical emergencies which may simulate acute coronary heart disease. Pulmonary embolism, aortic dissection, acute pancreatitis, spontaneous mediastinal emphysema, pneumonia—all may be confused with acute myocardial infarction. In these circumstances, however, the presentation is generally a sudden single event. The response of the physician to these acute situations must be immediate with a priority of diagnostic procedures based upon those treatable diseases which represent a threat of life. On the other hand, the approach to recurrent chest pain syndromes should be more contemplative with a special effort made to detect less serious alternatives to chronic coronary heart disease.

I Electrophysiology of atropine

a Sinus node and the atrial muscle

1 Sinus node automaticity The administration of atropine is a dose of 0 5 mg or more usually accelerates the sinus rate by direct parasympathetic blockade In addition to this positive chronotropic action atropine given in small doses intravenously can slow the sinus rate or less frequently, may produce a biphasic effect [3 6 43] The biphasic effect of atropine can also be seen immediately after a higher dose or even following intramuscular administration [44] A biphasic response is characterized by initial slowing of the heart rate which is usually followed within 2 to 3 minutes by a positive chronotropic effect The mechanism underlying the slowing effect of atropine is unclear Das and colleagues[43] believe that in addition to producing sinus bradycardia by a central action low doses of atropine inhibit cholinesterase or may influence the activity of the peripheral sympathic nervous system

The effects of atropine on sinus bradycardia and other manifestations of sinus node dysfunction have also attracted attention recently The response to atropine is variable In some patients atropine adequately increases the heart rate whereas in others the response to this drug is barely measurable This effect of atropine most likely depends on the cause of sinus bradycardia itself In other words a minimal response to atropine may be related to intrinsic disease of the SA node while a more satisfactory response *suggests an extracardiac origin or so called phys*iologic bradycardia [47] The usefulness of atropine in the evaluation of sinus node dysfunction will be discussed in more detail below

Automaticity of the SA node can also be evaluated by measuring the sinus node recovery time (SNRT) which is the duration of atrial asystole after rapid atrial pacing is discontinued It is believed *that this method is more sensitive* than pharmacologic tests in the differentiation of intrinsic sinus node dysfunction from physiological bradycardia The pause in atrial activity after discontinuation of rapid atrial pacing is mainly a measure of the functional status of the SA node and is longer in patients with decreased SA node automaticity than in those with normally functioning sinus node According to some authorities however the effect of rapid atrial pacing is more complex than simple inhibition of the automaticity of the SA node and the sensitivity *of this test for sinus node* dysfunction is low [3 47 4]

In general, atropine shortens the SNRT in normal individuals and in most patients with sinus node dysfunction [2 30 3 14] Atropine paradoxically prolongs the SNRT or produces a transient AV junctional rhythm when given to some patients with sinus node dysfunction [5 31] This paradoxical effect on *SNRT* may be mediated through the effect of atropine in improving sinoatrial conduction Because the number of impulses entering the SA node after atropine is greater the SA node itself will be suppressed Reiffel et al[1] suggested that this paradoxical effect of atropine on the SA node could also result from concealed conduction or from altered conduction within the SA node

2 Sinoatrial conduction Impaired automaticity of the SA node is only one function which can underlie sinus node disease Strauss and co workers [8] have suggested that another abnormality impaired sinoatrial conduction (SAC) may be involved This assumption has not been accepted by all For instance Scherf[5] and Dighton believe that SA block is a manifest*ation of* SA nodal disease rather than of true conduction defect On the other hand electrophysiological observations and experimental studies by Strauss and Bigger[54] point to the existence of true sinoatrial block

Sinoatrial conduction time can now be measured only indirectly using artificial atrial premature stimulation[48] or in *patients with* atrial parasystole as described by Langendorf and colleagues [55] By this method [48] the sinoatrial conduction time is calculated to be the difference between the basic cycle and the return cycle following introduction of an artificial atrial premature beat According to this concept antegrade and retrograde conduction between the SA *node and the atria are the* same and the artificial impulse only resets the SA node and has no influence on its automaticity

The effect of atropine on sinoatrial conduction time has also been studied by several groups of workers Among them Bissett and co workers and others [5 57 58] demonstrated a shortening of the sinoatrial conduction time after the administration of atropine to subjects with normal SA node function while Reiffel and Bigger[54] also showed improved sinoatrial conduction time in patients with sinus bradycardia On the other

The effect of atropine on cardiac arrhythmias and conduction Part 1

Paul Schweitzer M D F A C C
Herbert Mark M D F A C C
Bronx N Y

The effects of atropine on cardiac rhythm have been known since 1912 when Robinson and Draper[1] abolished atrial premature beats with the drug and 1915 when Wilson induced atrioventricular (A V) dissociation These results established a pattern of investigation for early workers who then concerned themselves with the effects of atropine on A V conduction More recently since the report of Agress and Binder the effectiveness of atropine in acute myocardial infarction complicated by bradycardia was investigated intensively In subsequent studies with atropine Thomas and Woodgate and Harris and Bluestone using atropine corrected both bradycardia and hypotension occurring in patients with myocardial infarction and in a more extensive series of patients Adgey and colleagues found that atropine corrected bradycardia and hemodynamic abnormalities and also suppressed ventricular premature beats As a result this clinical setting became the prime indication for atropine

Following introduction of intracavitary electrocardiography and pacing techniques the usefulness of atropine in the management of patients with sinus node dysfunction was assessed and its effect on the electrophysiological functions of the sinoatrial (SA) and atrioventricular (AV) nodes was analyzed

The number of studies reported increased and inevitably some confusion about the usefulness of atropine also arose as some studies led to apparently conflicting data and note was made of hazards arising from atropine s use

Accordingly in this review we will summarize the electrophysiological effect of atropine on the cardiac conduction system and myocardium and attempt to establish criteria and guidelines for its use and explain some of its seemingly conflicting and paradoxical effects

Best known of the cardiac effects of atropine is its ability to increase heart rate and facilitate A V conduction by its vagolytic action on the sinus node However atropine also exerts direct influence on the function of the AV junctional tissue and the subjunctional components of the specialized conducting system Some of the other effects of atropine are indirect and are probably related to unopposed action of the sympathetic nervous system or simply to an increased heart rate The response to atropine also depends on the varying sensitivity of different levels of the specialized conducting system to autonomic stimuli In fact under circumstances to be described not all components of the specialized conducting system will respond to vagal stimulation or blockade Furthermore the differing sensitivity to atropine of the various structures of the specialized conducting system may lead to unpredictable and apparently paradoxical effects

The amount of atropine necessary to produce complete blockade of the parasympathetic nervous system is uncertain According to some workers 2 0 mg of atropine should inhibit the vagus nerve while Jose and Chamberlain and co workers believe that as much as 3 to 6 mg of atropine is needed to block the vagus completely

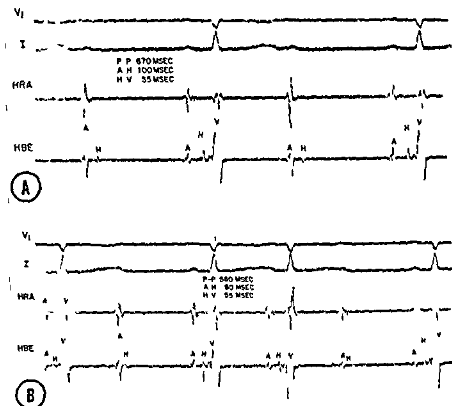

Fig 2 (Patient 2) The effect of atropine on second degree AV block *From the top to bottom* Lead V_1 I high right atrial electrogram *(HRA)* and His bundle electrogram *(HBF)* *A* there is a 2 1 AV block Each atrial deflection is followed by an H spike confirming the presence of a block below the AV node *B* five minutes after the administration of 1 0 mg of atropine the 2 1 AV block changed to 3 2 AV block

the pacemaker localized in the distal part of the His bundle can also respond to autonomic stimuli[62, 64]

2 *Atrioventricular conduction* Facilitation of AV nodal conduction by atropine in patients with normal AV nodal conduction is a well known effect Akhtar and colleagues[37] and others[38] demonstrated that atropine improves AV nodal conduction and decreases both the effective and functional refractory period of the AV node Further second degree AV block is achieved at higher pacing rates after the administration of atropine Shortening of AV nodal conduction time is manifested regardless of the dose of the drug administered[4]

The effects of atropine on first degree AV block from different causes are variable and unpredictable[4, 7] In second degree AV block the response to atropine is more consistent In general type one second degree AV block will disappear after the administration of atropine while the drug tends to be ineffective in type two second degree AV block[65, 7]

Dual AV nodal pathway (DAVNP) is a not uncommon condition characterized by the presence of two intranodal pathways with different refractoriness and conductivity[68] One pathway which conducts the atrial impulse faster usually has a longer effective refractory period whereas the second pathway through which the impulse travels more slowly tends to have a shorter effective refractory period Neuss and co workers[69] studying the effect of atropine in eight patients with DAVNP abolished the DAVNP in four while in three patients the drug was ineffective and in one case DAVNP was unmasked by atropine Recently Akhtar and co workers reported five patients in whom neither atrial pacing nor atrial extrastimulation induced paroxysm of supraventricular tachycardia at rest while following administration of atropine atrial premature beats initiated a supraventricular tachycardia It is likely that in this study atropine unmasked a DAVNP which is now assumed to be a necessary electrophysiological abnormality for initiation of a reentrant tachycardia[11]

c His Purkinje system and ventricular muscle

1 *Automaticity of the His Purkinje system* A influence of the parasympathetic nervous syste

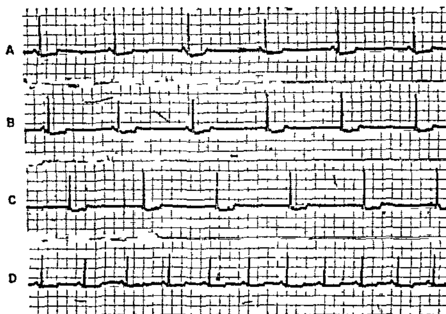

Fig 1 (Patient 1) Atropine-induced AV junctional rhythm *A* sinus bradycardia with a rate of 37/minute *B* and *C* two minutes after the administration of 1 0 mg of atropine there is an AV junctional rhythm and AV dissociation *D* sinus rhythm at a rate of 74/minute resumes five minutes after the administration of atropine

hand Dhingra and associates[57] found that while atropine shortens sinoatrial conduction time in normal patients it does not have this effect in the presence of sinus node dysfunction

3 Atrial muscle Reports of the effect of atropine on the refractoriness of atrial muscle in man are few and also conflicting Some authors[7] found shortening of the effective refractory period of the atrial muscle in normal individuals after atropine but others have not been able to confirm these findings[37] [8] nor does atropine significantly influence the effective refractory period of the atrial muscle in patients with sinus node dysfunction according to Dhingra and co workers[5]

b Atrioventricular junction

1 Atrioventricular junctional pacemaker Atropine stimulates the atrioventricular junction pacemaker in normal patients and in those with sinus nodal disease In normal subjects the increased activity of the AV junctional pacemaker becomes evident immediately after the administration of atropine when the drug temporarily suppresses the SA node and stimulates the subsidiary pacemaker

This effect is demonstrated by the following patient A 72 year old man was admitted because of syncope The ECG on admission showed sinus bradycardia with a rate of 37/minute (Fig 1*A*) Two minutes after the administration of 1 0 mg of atropine there was a slight decrease of sinus rate after which AV dissociation appeared (Fig 1*B* and *C*) Five minutes following the administration of atropine the sinus rhythm increased to 74/minute (Fig 1*D*) and the AV dissociation was abolished

In some patients with sinus node dysfunction the resulting AV junctional rhythm can last for as long as 3 hours The mechanism for this sustained AV junctional rhythm is not well understood We suggest that in these patients the SA node becomes unresponsive to automatic stimuli, permitting the effect of atropine on the AV junctional pacemaker to become dominant

Atropine may also be useful in helping to localize the level of the block in patients with complete AV block and narrow QRS complexes Narula and associates[59] studying the effect of atropine in 11 patients with these electrocardiographic features noted that atropine increased the rate of the escape pacemaker in five patients and had no effect on the subsidiary pacemaker in the remaining six They postulated that in patients who responded to atropine the subsidiary pacemaker was in the AV junction while the nonresponder had the escape pacemaker within the His bundle These results have been confirmed[6] [61] but recent case reports suggest that

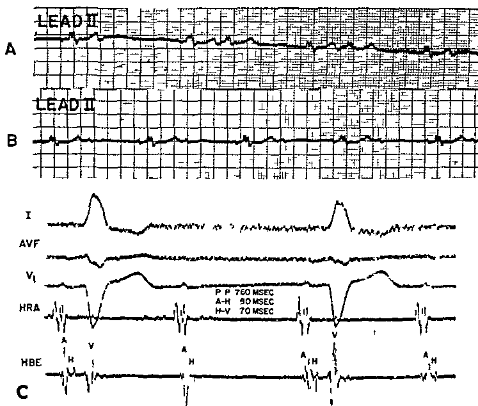

Fig 4 (Patient 3) The effect of atropine on second degree AV block *A* atrial bigeminy the atrial beat after the first and fourth beat is blocked *B* administration of 1 0 mg of atropine suppresses the atrial premature beats and produces a 2 1 AV block *C from top to bottom* Lead I aVF V high right atrial electrogram *(HRA)* and His bundle electrogram *(HBE)* 2 1 AV block localized below the AV node is demonstrated

with shortening of the A H interval (Fig 2*B*) After an acute inflammatory or ischemic disease had been ruled out by appropriate study the patient underwent exercise testing The resting ECG showed 3 2 AV block (Fig 3*A*) During exercise there were short episodes of 1 1 conduction despite a rapid sinus rate (Fig 3*B* *C* and *D*)

Finally atropine also has a paradoxical effect on AV conduction by causing AV block or increasing a pre existing conduction abnormality Most patients responding in this manner had conduction defects below the AV node [7] or acute myocardial infarction The apparent paradoxical effect of atropine in patients with subnodal conduction defect probably results from an increased sinus rate which unmasks the conduction abnormality below the AV node

Our third case illustrates this effect of atropine The patient is an 82 year old man seen in the emergency room because of dizziness The ECG showed sinus rhythm with the rate of [illegible] minute and frequent atrial premature beats some of them blocked A rhythm strip (Fig 4*A*) shows atrial bigeminy Administration of 1 0 mg of atropine increased the sinus rate to 83/minute suppressed the atrial irritability and initiated a 2 1 AV block (Fig 4*B*) Thirty minutes after the development of the AV block a His bundle electrogram was recorded (Fig 4*C*) The intracavitary recording demonstrated the conduction defect below the AV node Atropine not only suppressed the APC s but also uncovered an AV conduction disturbance

Worsening of AV conduction or development of paroxysmal AV block in patients with acute myocardial infarction after the administration of atropine has been reported [77, 78] The localization of AV block caused by atropine in these patients was not confirmed by His bundle recording and therefore we do not know at what level the AV conduction was impaired Because some of these reported patients had inferior myocardial infarction in which the block is usually localized in the AV node it is assumed that atropine caused a conduction disturbance within the AV node

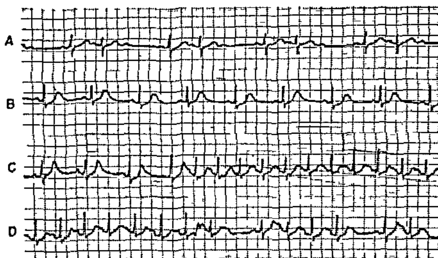

Fig 3 (Patient 2) The effect of exercise on second-degree AV block Lead V *A* resting ECG shows 3 2 AV block with an atrial rate of 93/minute *B* during exercise the atrial rate increases to 135/minute and the AV block changes from 3 2 to 2 1 *C* and *D* transient 1 1 conduction is noted at the same atrial rate as in *B*

on the automaticity of the His Purkinje system was postulated in patients with advanced AV block and idioventricular rhythm by Schwartz and de Sola Pool[8] who demonstrated that atropine increases the idioventricular rate and also suppresses ventricular irritability in patients with third degree AV block Following a renewal of interest in this problem recent studies suggested that the subnodal portion of the His Purkinje conducting system is indeed under parasympathetic influence Bailey and co workers[72] showed that in in vitro preparations acetylcholine decreased phase four diastolic depolarization in the proximal part of the intraventricular conducting system Danilo and associates[73] demonstrated the same effect on the Purkinje system and also showed that atropine blocks the effect of acetylcholine on the intraventricular conducting system

Existence of parasympathetic innervation of the subjunctional specialized conducting system was also confirmed by Kent and co workers[74] The response of the intraventricular conducting system to parasympathetic stimulation is further supported by Waxman and Wald [5] who were able to interrupt ventricular tachycardia in humans by vagal stimulation Finally the previously discussed response of the subjunctional pacemakers to autonomic stimuli is consistent with these experimental findings [64] On the other hand Narula and colleagues and others [6 6] believe that the subjunctional pacemakers are insensitive to vagal stimulation

2 *His Purkinje system conduction* The effect of atropine on subjunctional conduction is also unclear It is generally believed that a conduction disturbance below the AV node will not improve or may even be aggravated after the administration of atropine [65 6]

Patients with conduction disturbance within the His bundle are the most suitable group in which to test the effect of atropine on subnodal conduction According to Gupta and colleagues [7] there are patients with intra Hisian block in whom atropine improves conduction but the response to atropine of the subjunctional conducting system is less predictable The reason for this variable effect of atropine on the conduction through the His bundle is unclear One can speculate that the response to atropine depends on the site of conduction defect within the His bundle That is to say atropine is more effective in a proximal than in a distal intra Hisian block [76]

The effect of atropine on AV conduction in our next patient supports our contention that there are important subjunctional parasympathetic effects The patient is a 46 year old man with a history of dizziness of one day duration The electrocardiogram on admission showed 2 1 AV block Subsequently a His bundle electrogram was recorded before and after 0 1 mg of atropine following which a temporary pacemaker was inserted into the right ventricle The His bundle recording demonstrated a block below the AV node (Fig 2A) Administration of atropine increased the heart rate from 89/minute to 107/minute and the block changed from 2 1 to 3 2

44 Hayes A H Copelan H W and Ketchum J Effects of large intramuscular doses of atropine on

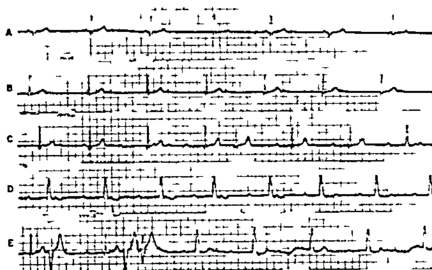

Fig 5 (Patient 4) The effect of atropine on the sinus node and AV conduction in a patient with inferior myocardial infarction Lead I *A* before administration of atropine there is sinus bradycardia at a rate of 36/minute and sinoatrial block The fourth and seventh beats are AV junctional escape beats *B* the sinus bradycardia is replaced by AV junctional rhythm at a rate of 36/minute after the administration of 1.0 mg of atropine *C* the AV junctional rhythm lasted for one minute after which sinus rhythm complicated by high grade AV block appeared Only the fifth sinus impulse is conducted into the ventricle The ventricles were controlled by an AV junctional pacemaker *D* the AV block persisted and the QRS complex become wide measuring 0 11 sec The rates of the narrow and wide QRS complexes were the same (38/minute) *E* the first two narrow QRS complexes precede ventricular premature beats. Elsewhere the QRS complexes are wide From *C* to *E* there is a progressive increase of the atrial rate from 60/minute to 100/minute

However this assumption requires confirmation because the situation is probably more complex and atropine may unmask impairment of conduction at more than one level as is indicated by our fourth patient

The patient a 42 year old man was admitted with an acute inferior myocardial infarction On the tenth day in the hospital after an uncomplicated initial course the patient developed syncope An ECG taken at that time showed sinus bradycardia with a ventricular rate of 36/minute sinoatrial block and AV junctional escape beats (Fig 5*A*) Atropine in a dose of 0 5 mg was ineffective and therefore a second dose of 0 5 mg of atropine was administered after which the sinus rhythm was transiently replaced by AV junctional rhythm with a similar ventricular rate (Fig 5*B*) Following resumption of sinus rhythm (60 to 80/minute) an advanced AV block developed together with intermittent widening of the QRS complex and ventricular premature beats (Fig 5*C* *D* and *E*) The increased duration of the QRS could be due either to an idioventricular rhythm or to aberrant conduction of the AV junctional beats Because the heart rate did not change significantly aberrant conduction is a more likely explanation for the wide QRS complex than is an idioventricular rhythm A temporary pacemaker was inserted into the right ventricle and the patient made an uneventful recovery In this case atropine improved sinoatrial conduction and sinus node automaticity and at the same time unmasked latent AV and intraventricular conduction disturbances This second effect of atropine occurred after the drug increased the sinus rate The exact localization of the block is uncertain without His bundle recording The conduction defect was probably localized below the AV node because both AV and intraventricular block were present

According to Guss and colleagues ° atropine does not significantly influence the refractoriness of right ventricular muscle This observation is consistent with the findings of Kent and co workers who showed that the parasympathetic innervation of ventricular muscle is sparse in comparison to the rich cholinergic innervation of the intraventricular conducting system

Annotations

Of papillary muscle dysfunction murmurs

It was not made sufficiently clear that the murmur of papillary muscle dysfunction can have almost any imaginable characteristics with regard to both the time course of intensity and/or frequency. The French clinicians were correct when they referred to the heart sounds and murmurs as noises. The only characteristics common to all papillary muscle dysfunction murmurs are that they originate from the mitral valve and are systolic in time. Thus their location and transmission and referral are the same as for any murmur of mitral insufficiency. The time course of the level of the pressure gradient across the mitral valve and the size and shape of the orifice through which the leak occurs and the time course of all three of these factors with respect to each other will determine as expected the characteristics of the murmur of papillary muscle dysfunction. This is also true of all heart murmurs.

Pacemaker annihilation diagnostic and therapeutic implications

Over the years clinical cardiologists have searched for electrocardiographic clues to distinguish between reentrant and pacemaker mechanisms of cardiac arrhythmias. For example it has been assumed that if a properly timed stimulus applied through external or intracardiac electrodes can terminate an episode of tachycardia then the mechanism must have been reentrant; a single stimulus would not be expected to suppress the spontaneous firing of an ectopic pacemaker. Unfortunately recent electrophysiological experiments have demonstrated that the validity of this diagnostic criterion is questionable.

Spontaneous pacemaker activity in cardiac pacemakers is characterized by rhythmic oscillations in their membrane potential. The mechanism of pacemaker depolarization in cardiac Purkinje fibers, sinoatrial nodal cells, and in working myocardial cells undergoing spontaneous activity induced by steady depolarizing current has been studied by voltage clamp experiments. In all cases pacemaker activity has been attributed to a cyclical voltage-dependent potassium current. This current has non linear features such as anomalous rectification and negative conductance and it gives the pacemaker feedback characteristics that are common to other biological oscillators. Spontaneous activity in cardiac pacemakers can be modulated by stimuli from their natural surroundings.

In general, if the spontaneous firing of a pacemaker is kicked off its stable cycle by a brief electrotonic stimulus or by a transient vagal burst it very soon resumes its previous rhythmic activity with the same cycle length but generally with a new phase in relation to the previously unperturbed rhythm. The magnitude and direction of this phase sh... depend on the time of stimulus application. This is illustr... in Fig 1A which shows a phase response curve (PPC) obt... from a spontaneously beating Purkinje fiber mounted ... sucrose gap chamber (for method, see Ref 9) and firing ... an average basic cycle length (BCL) of 1 600 msec (max... diastolic potential MDP = −8? mV). The curve shows delays and accelerations (positive and negative ΔBCL, re... tively) effected by brief depolarizing current pulses (?00 m... 0 8 μA) as functions of the time of stimulus application ... expressed as percent of BCL.

In most experiments these effects are transient and ... pacemaker rapidly returns to its free-running activity. How... er in some preparations pacemaker activity can be term... nated with a single stimulus applied at the proper time. Fig 1B shows analog records from the same experiment when the membrane potential of the pacemaker was continuo... depolarized with a bias current step of long duration. Under these circumstances MDP decreased to −?0 mV and the pacemaker was beating at an average BCL of 1 4?0 msec in the steady state. As the pacemaker cycle was scanned with a depolarizing current pulse of the same duration and magnitude as in *panel A* of Fig 1 a critical phase in the cycle was f... reached during which current pulse application was f... by subthreshold oscillations. These oscillations either beca... progressively larger and eventually reached threshold (Fig 1, *panel B2*) or they damped and resulted in complete a... tion of pacemaker activity (*panel B3* pacemaker act...

Common sense and clinical chemistry

The evolution of clinical chemistry over the past 20 years has been a curiously uncontrolled process Clinical chemistry is an applied science whose primary function is to provide information which is relevant to the diagnosis and management of patients. Decisions about which constituents of body fluids should be measured are based on the ease with which measurements can be made and the clinical relevance of the tests Unfortunately the former consideration has always weighed more heavily than the latter As a result of the spectacular advances in methodology and automation since the 1950 s many biochemical substances can now be measured with great speed and precision The exponential growth in the workload in clinical chemistry departments which shows little sign of abating testifies to the enthusiasm with which these advances have been welcomed by both clinicians and clinical chemists Unfortunately both groups appear to have lost sight of the need for at least a modicum of clinical relevance to justify the explosion. Consequently the exponential decay rate of the proportion of tests which serve any real purpose is higher than the workload growth rate

In my own hospital in the absence of any significant changes in the management of water and electrolyte balance the numbers of plasma sodium measurements have risen by 600% over 13 years Apart from the steady rise prompted by the assumption by clinicians that they have been negligent if any patient escapes from the hospital without an electrolyte estimation there were sharp increases in 1965 when with the introduction of a new flame photometer it became automatic that the sodium was measured whenever the blood urea nitrogen was requested which doubled the sodium numbers overnight and in 197_ when a Technicon multichannel electrolyte analyzer was purchased

The workload in almost any general hospital today will be too large and the technical staff too small to make it feasible to be totally selective in biochemical tests but it is important to differentiate groups of investigations which have some functional biochemical relationship from those which are related only because of the organization of analytical machinery It is justifiable to report plasma sodium potassium chloride bicarbonate and urea nitrogen together when ever one of these tests is requested because of the way in which deviation from normality of each is often related to deviations in the others When however liver function tests are provided gratuitously whenever electrolytes are requested or the serum uric acid is automatically added to a bone profile because it is felt that all tests should be part of a profile and joints are anatomically related to bones then the clinical disadvantages rapidly outweigh the initial convenience to the laboratory and subsequently the laboratory is swamped with unnecessary repeat requests

The whole philosophy of biochemical screening is based on a failure to relate biochemical findings to the management of disease It is often suggested that one aim of clinical chemistry should be to detect and follow up disease as early as possible. Ischemic heart disease is cited as an example where a dedicated approach would be both individually beneficial and economically sound This proposal confuses theory and fact and ignores practicality There is no clearly recognized biochemical predictor of ischemic heart disease no clear line of prevention and no way of persuading patients to eat less, give up smoking worry less and exercise more even if one were convinced that these were effective measures and the implementation of such a management program would provide more than full time occupation for all the country s doctors and nurses

Even in diabetes mellitus which is the disease most likely to be revealed by biochemical screening and where there is at least a clearer although by no means absolute relationship between a single biochemical test the blood glucose and the incidence of cardiovascular renal and neurological complications there is still no evidence that the detection of an elevated blood sugar before the onset of clinical signs is of any value either in the short or in the long term

There have been several reports of the almost total failure of communication elicited by the battery of unexpected abnormal results produced with the profile screening The volume of work which this approach itself generates is considerable Of 2 000 patients who had an admission profile of 1[?] biochemical tests 3[?]% had at least one unexplained abnormal result for a test which had not been requested The immediate

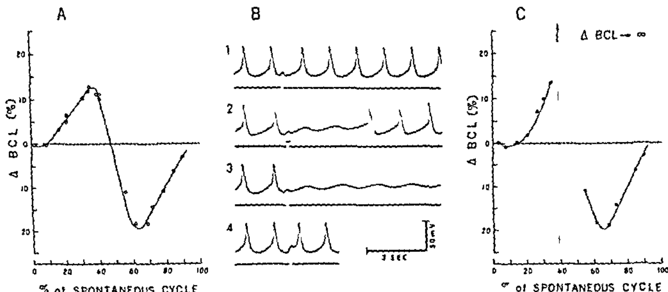

Fig 1 Phase resetting behavior of a Purkinje fiber pacemaker *A* Phase response curve (PRC) obtained from a Purkinje fiber sucrose gap preparation by scanning the pacemaker cycle with brief subthreshold depolarizing current pulses *B* Microelectrode recordings from the same preparation using current pulses of the same duration and magnitude but following a change of the steady state maximum diastolic potential to −60 mV by the application of bias current *C* PRC from a complete scan in the run illustrated in *panel B* The vertical arrow indicates the phase of the spontaneous cycle at which annihilation occurred (38%)

could be restored by the application of a second brief pulse of larger intensity) If the same stimulus (200 msec 0 8 μA) was applied at a different phase in the cycle it merely delayed (Fig. 1 *panel B1*) or accelerated (*panel B4*) subsequent discharges *Panel C* illustrates the PRC obtained under these conditions and shows that the annihilation phenomenon (ΔBCL → ∞) was only observed when the perturbing stimulus was presented between 36 and 52% of the spontaneous cycle When the duration or the amplitude of the current pulse was changed or when the membrane potential was returned to more negative levels (−64 to −91 mV) by decreasing the strength of the bias current pacemaker activity could not be terminated with a single stimulus and the PRC returned to its original shape (Fig 1A)

The phenomena we have just described are not unique to the isolated Purkinje fiber We have been able to annihilate the spontaneous rhythm of isolated SA nodal cells G Ferrier (personal communication) has obtained similar results in working muscle preparations in which repetitive activity was induced by depolarizing bias current and Wit and Cranefield have reported a similar phenomenon in simian mitral valve fibers undergoing triggered automatic activity In fact phase resetting behavior and annihilation phenomena have been observed in a variety of self-sustaining oscillatory systems including circadian rhythms neuronal pacemakers and bio chemical oscillators Common to all systems is the fact that an exact combination of stimulus timing duration and magnitude annihilates the pacemaker rhythm

Although direct extrapolation is difficult the experimental and clinical implications of these phenomena are obvious in terms of mechanism diagnosis and treatment of cardiac arrhythmias. As we have suggested in previous studies classical criteria to differentiate between reentrant and pace maker mechanisms based on the analysis of the electrocardio gram will have to be re examined The experiments outlined above further strengthen this contention and they demon strate together with the experiments of Ferrier and co workers and of Wit and Cranefield that the fact that a single stimulus can terminate a tachysystolic arrhythmia can no longer be taken as an absolute proof of reentry Further more the existence of these phenomena in cardiac pacemakers should be taken into account when analyzing the success or failure of therapeutic measures such as the drug treatment of ventricular parasystolic and other extrasystolic arrhyth mias

implication is that every third profile will if the clinician reads the report generate the fourth However five years later follow up of 200 of this group of patients revealed that only three had results indicative of presymptomatic disease and the authors voiced doubts about the prognostic significance of early diagnosis even in these In this situation clinicians confronted with an unexpected laboratory value which deviates from the normal range rapidly learn to consider it clinically insignificant and ignore it After repeated exposure to such values they become increasingly prone to ignore everything the laboratory reports, and this includes those results which require action

On the basis that information to be transmitted to clinicians should have direct relevance to the management of their patients its quantity should be as small as possible consistent with this aim The clinical chemist s ability to generate adequate laboratory information even in relation to discretionary tests is already very considerably greater than the clinician s ability to use it The charitable urge to produce information which has not been requested because it can easily be made available should be resisted as far as possible Manufacturers of analytical machinery have stepped in with glee to profit from the loss of control of the medical profession over the investigation of their patients and have increased the momentum with which we are racing in the wrong direction by producing ever larger machines with ever more channels It is legitimate for the manufacturers to think only in terms of the money they can make Doctors should be swayed by other considerations of which not the least important is common sense

Romano-Ward syndrome treated by left stellectomy and intracavitary stimulation

In the June 1976 issue of THIS JOURNAL we reported the case of a patient with congenital QT segment prolongation (Romano-Ward syndrome)

In view of the small number of reported cases and the uncertainties regarding the accurate treatment of that ominous disease responsible for sudden death by torsades de pointe we think it interesting to report briefly the outcome of the original mode of therapy applied in this case

The case of the patient M F D was satisfactory until January 1978 with occasional palpitations

In spite of the sustained administration of propranolol 20 mg 4 times daily and digitalin 0 1 mg five time weekly she was seized in February 1978 by short lived convulsions. In March 1978 severe and repeated spells of torsades de pointe were discovered which were abolished by a temporary intracavitary stimulation After lignocaine blocking of the left stellate ganglion a shortening of the QT interval was observed from 0 48 to 0 42 sec under intracavitary stimulation at 120 impulses per minute (Fig 1) A left stellectomy involving the inferior two thirds of the ganglion was then performed by the axillary way which resulted in an incomplete Horner s syndrome (pupillary constriction without enophtalmos or ptosis)

Subsequent ECG recordings showing a persistent lengthening of the QT interval between 0 52 and 0 60 sec (Fig 2) the installation of a permanent intracardiac pacemaker was decided upon with a programmable Cordis Omnistanicor set at 90 impulses per minute This procedure was followed by the complete disappearance of syncopes and palpitations Various ECGs and 24 hour ECG recording (Holter monitoring) revealed a good control of the rhythm by the implanted pacemaker with rare conducted atrial beats whose QT inter

Central retinal vein thrombosis in a patient with primary pulmonary hypertension

Prophylaxis of venous thromboembolism

To the Editor

Dr. Bland [illegible] in his Editorial on [illegible] prophylaxis of deep vein thrombosis has reached some conclusions which are open to question. He suggests that a [illegible] venous thrombi are not in terms of morbidity important. If we [illegible] in a survey of the clinical features of pulmonary embolism [illegible] Bell and colleagues found that less than a quarter of their patients with angiographically proven emboli had

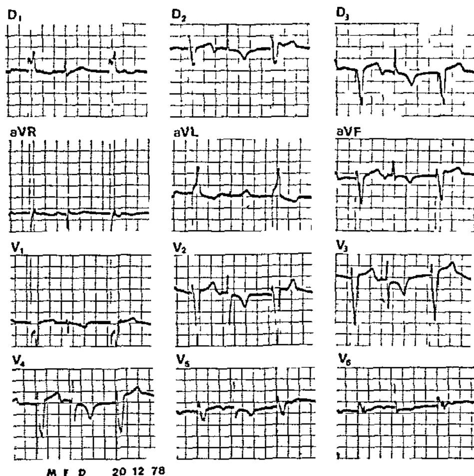

Fig 3 Same patient as in *Fig 1* The ECG shows good stimulation by the pacemaker and conducted beats with a normal QT interval

val was normal (Fig 3) To our knowledge this is the first report of left stellate ganglionectomy associated with the implantation of a pacemaker with a relatively high preset rate of stimulation This kind of treatment seems to be logical and effective Left stellectomy alone while being the treatment of choice in the Romano Ward syndrome of some authors resulted for others in inconstant improvement short lived shortening of the QT interval or even complete failure

On the other hand intracavitary stimulation prevents bradycardia common in the Romano Ward syndrome and increased by the beta blocking agents

Slow cardiac rates induce asynchronous repolarization and ectopic beats Finally thi report points to the important part played by sympathetic imbalance in the genesis of the Roma no Ward syndrome

ower limb symptoms. It appears then that asymptomatic hrombi can commonly give rise to pulmonary emboli It is ot yet possible to predict which emboli are likely to embolize Therefore for the present it is rational to consider prophylac c measures which reduce the incidence of all thrombi ymptomatic or not

Dr Blaisdell points out that the I fibrinogen uptake test ommonly used in clinical studies of thrombosis is less ensitive in the thigh and pelvic veins than it is in the calf The est is often criticized on this basis since most pulmonary mboli are said to originate in the larger more proximal veins However in an extensive autopsy series Havig found that mong 120 patients with pulmonary embolism the most roximal thrombi were below the knee in 43 cases. Twenty ve percent of lethal emboli originated in the calf Further nore it appears from venographic[4] and autopsy studies that he majority of thrombi arise in the deep veins of the calf Most thrombi involving the popliteal femoral and iliac veins re continuous with or associated with calf vein thrombi and would therefore be detected by the I fibrinogen test In view f this we conclude that for *clinical trials* of prophylactic egimes the I fibrinogen uptake test remains the method of choice for detecting deep vein thrombosis

A very useful follow up test to the I fibrinogen scan is radioisotope venography using radiolabelled macra aggregates of albumin This is less invasive than conventional x ray venography and appears to be as accurate in the thigh and pelvic veins. The radiolabelled particles cleared from the leg will also provide a perfusion lung scan It is thus a particularly valuable follow up to a positive I fibrinogen test

We agree with Dr Blaisdell that the use of standardized low doses of heparin while practical in the case of patients undergoing a routine operative procedure such as hip surgery is not reliable in patients who may be suffering from severe trauma sepsis shock, or multiple organ failure Perhaps what is needed now are trials in which the dose of heparin is adjusted for each patient to a standard end point (mean plasma heparin concentration or activity) In seriously ill patients the use of relatively noninvasive techniques such as the I fibrinogen test and the bedside isotope venogram would be essential

Advances in the Management of Clinical Heart Disease vols II and III Edited by Jacob I Haft M D and Charles P Bailey M D Mount Kisco N Y 1978 Futura Publishing Company Vol II 308 pages Vol III 280 pages Price each volume $19 75

These two volumes represent the proceedings of the Second Saint Michael s Medical Center Cardiology Symposium on *Advances in the Management of Clinical Heart Disease* Volume II is concerned primarily with coronary heart disease viz myocardial infarction and angina pectoris The surgical and medical managements are discussed but this reviewer finds it difficult to understand the data and recommendations especially as related to the surgical results and recommendations. For example on page 298 the reference to Mullen and associates, it is stated there were no survivors in this series of 60 patients who had a low preoperative cardiac index and absent septal motion judged by the left anterior oblique ventriculogram Despite these observations their operative and late mortality was only 3 3 and 8.3% respectively Therefore what are late results? What about the interpretation of this statement? The ordinary practicing family doctor will not find this volume to be useful and the cardiologist who follows the literature already has his information and plans in practice

Volume III is concerned with three aspects of cardiovascular disease namely therapeutics hypertension and echocardiography There are rather brief discussions of the management of arrhythmias, cardiac pacing dissecting aneurysms of the aorta, valve surgery sensitivity to cardiac glycosides and hypertension and the use of echocardiography in the evaluation of valvular heart disease These presentations are intended for the practicing physician but are at the level of cardiologists to a major extent such as the use of cardiac pacing and echocardiography The family physician will learn of the recommendations and practices of the contributing authors The discussions are not presented critically for the benefit of the readers who are fully trained cardiologists These two volumes are of some interest but are not outstanding

Clinical Nuclear Cardiology Edited by Robert W Parkey M D Frederick J Bonte M D., L Maximilian Buja M D and James T Willerson M D New York 1978 Appleton Century Crofts Inc 338 pages Price $?8.50

This book describes a new subspecialty of nuclear medicine and of cardiology But is its value in clinical medicine yet established? The many contributors to this book review the field for clinicans rather thoroughly The editors of the publication fail to indicate established indications for the use of radioactive elements and nuclear medicine in cardiology The contributors do present adequately what is now the practice There is a need to know for example whether or not direct intracoronary injection of a nuclide justifies the cost and risk Furthermore it is yet to be shown that the information sought is derived or even equal to that obtained by the well established clinical procedures. Those who record electrocardiograms properly and can interpret them surely do not need myocardial imaging to detect locate and learn the size of an infarct of the myocardium Regardless the book in 15 chapters, reviews the field well. The illustrations are good and the subject is discussed so that the reader will learn applications of nuclear medicine to cardiology

Advances in Cardiology Sudden Coronary Death Vol 25 Edited by Vesa Manninen and Pentti I Halonen Basel, Switzerland 1978 S Karger AG Medical and Scientific Publishers 231 pages Price $77 00

This is another excellent volume of *Advances in Cardiology* It contains interesting and important discussions. For example physical activity and sudden death life changes and sudden death cardiomyopathy and sudden death neural influence and sudden death the role of the coronary ambulance and sudden death and the coronary care unit and sudden death are among the discussions. This is a valuable book which is easy to read and is concerned with an important problem sudden death The book should interest all doctors.

into displacement activity keeps them too busy to deal with the business in hand—which should be preparing to go back to their lives as winners instead of losers. The physician's urging them to stay out of bed and return to work quickly colludes with their morbid desire to die rather than submit to enforced quietude. Deprived of room for maneuver[14] and having learned nothing from the experience of breaking down, they may hasten back to the same old problems with the same old tactics and break down again and again at five times the rate of their more passive (Type B) brethren who may have been overcome by chronic overloading at work, serious life dissatisfaction, bereavement, helplessness, sleeping difficulties, domestic disharmony, and attempts to adapt or habituate to life changes which outstripped their strength and coping ability.[1, 3, 21, 3] It is easy to suppose that the ability to resist a coronary breakdown diminishes as the coronary arterial abnormalities increase, but we know that it can take place irrespective of the severity of the coronary arteriographic picture[3] and many people with severe arterial abnormalities appear to lead vigorous lives and support heavy burdens without breaking down their health by forcing storms of excessive demands upon their coronary circulation.

In Schumacher's exercise we should put it down on the maps that few of the unfortunate maintain intact homeostasis before the breakdown.

Most of them have arrived at angina, acute coronary insufficiency, myocardial infarction or sudden death after a long period of exhaustion.[4] This itself causes disability because the heart rate rises excessively in response to physical and emotional challenges and the blood pressure climbs too high for too long in response to common or garden stimuli. Relatively small amounts of exercise produce the symptoms previously associated with severe effort and the coping ability is much reduced in these subjects who are played out by continuous work, disturbed sleep and continuous strain, or exhausted by constant strain day and night, affected by sleeplessness, unable to go away and leave their posts. It is now accepted that profound abnormalities of the blood lipids, sugar, uric acid, and coagulability, and defects of many other systems are likely to result from severe and prolonged struggles.[2, 1]

It is not known how exhaustion produces this condition of sympathoadrenal hyperactivity and instability,[12, 1] where homeostasis has such a weak grasp of the internal milieu, but it does seem to underlie most cases of paroxysmal arrhythmia, angina pectoris, acute coronary insufficiency and hypertension, and common sense dictates the need to reverse it before good health can be recovered. If we fail to reverse it we may be tempted to adopt symptomatic remedies such as long term beta blockade, or even open heart surgery if arteriography happens to show seductive coronary arterial narrowings.

On my map it would be shown prominently that the unfortunates who suffer a coronary breakdown in health have certain basic needs. They require adequate rest[11] and good sleep[1] to overcome exhaustion and defeat, and to recover a stronger homeostasis; it can still be taken as axiomatic that if the patient does not get sufficient sleep he will never get well.[1] They need the support of warm and close human protection during their period of helpless dependence and adequate relief of pain, anxiety and despair.[1] They need time and room for maneuver to work out where they went wrong and to choose fresh tactics for the future.[21] Usually they need a commanding influence to keep them out of the battle for long enough to get well. Above all, they need to be trained to get fit enough and tough enough to go back to their lives as winners, avoiding the old self-destructive patterns of behavior which may have been derived from a defective social education, from loneliness,[7] perhaps from growing up in a footloose society[7] or from life in an area of recent emergence from poverty.[11] Most need to improve their ability to deal with time pressures[1] and information input overloading.[21] Many have to be shown that they need not despair of becoming well merely because Aesculapians have failed to cure them with the drugs and operations which happen to be fashionable at the time.[4]

Aesculapians whose maps do not show these basic needs prominently may be ignorant of the arrhythmic hazards of emotional arousal[4] and the antiarrhythmic importance of sleep, and so they may increase the hazards of myocardial infarction by putting people into depersonalised intensive care units amongst frightening technological paraphernalia. They may compare the effects of one

The responsibility of the cardiological mapmaker

P G F Nixon F R C P
London England

> The task of the philosopher is to provide a map of life and knowledge which exhibits the most important features of life in their proper prominence
>
> E F Schumacher 1977[1]

E F Schumacher suggests that the last three centuries of aggressive scientific imperialism have given us bewildering maps which omit most of the features that really matter because the mapmakers have concentrated on things which allegedly could be proven their first principle was If in doubt leave it out Since the question of what constitutes proof is subtle and difficult Schumacher recommends the exercise of turning the principle into its opposite and saying If in doubt show it prominently This exercise is useful to the cardiologist because his clinical duties oblige him to deal with large and important features which cannot yet be measured (unless he restricts his life to the laboratory) and as a mapmaker for patients and students he cannot evade his obligations to point out the routes of choice

In the coronary field the first step in the exercise must be for the cardiologist to decide whether he is an Aesculapian godsent to cure the disease or a disciple of Hygeia believing that his main responsibility is to find out where the patient s life went wrong and teach him how to get back on the good health which was his birthright After half a century of neglect it looks as though Hygeia may come into her own again because doctors who can enter into their patients lives are still insisting that behavior and circumstances can have profound effects upon the cardiovascular system and science is providing increasing support for their opinions by revealing the morbid effects of some aspects of life experience in susceptible persons

In this exercise our maps should show quite plainly that many coronary patients have a behavior problem and the younger they suffer the coronary breakdown the more serious the problem is likely to be Most of them are strivers and achievers restlessly addicted to work and tension guilty when wasting a minute enjoying the attack but never gratified by achievement (Type A) and capable of driving themselves far beyond the range of their homeostasis s ability to maintain a normal internal milieu[6 7 13 1 3 6 33] The coronary breakdown is often their comeuppance occurring either when they allow themselves to suffer defeat at the hands of others or when they defeat themselves by running out of time or strength[1 3] There are a number of good reasons why they consistently conceal this from the interrogator the burdens of explanation are too great[31] denial moves in to conceal their inadequacies from themselves and others[11 31 3 3] arrhythmic and self destructive life styles are presented as normal and the psychological need for escape

Schumacher s exercise of showing prominently the features which many omit from their maps because they regard them as in doubt unmeasured and unproved The emotional reaction of the reader is more likely to depend upon his philosophy than upon the measured and proved needs of his patients Is this as it should be?

antiarrhythmic drug with another and never state whether their acute care units help the recovery of homeostasis or incubate sudden death After the acute phase of the illness they may provide a relatively inflexible program of activity[5] which scarcely fits any particular patient because they think of themselves as dealing with a disease and not as serving people with infinitely variable coping abilities and circumstances

These Aesculapians can make extraordinary errors with patients suffering from angina pectoris because their maps do not show that the majority will get well if they follow the ancient rules of taking care to sleep well to avoid exhaustion and above all to avoid producing angina[2, 4, 8, 3, 31, 5] each attack of which overdistends the left ventricle and creates the risk of replacement fibrosis or fatal arrhythmia [31] Instead of being given the ancient rules the patient is likely to be given a map which overemphasizes risk factors of dubious value[33] Far from attending to the basic needs and encouraging obedience to the ancient rules the Aesculapian may create drug trials in which the patient is actually *encouraged* to produce pain in his daily life and invited to keep a trinitrin count[1] And once again the published trials compare one drug with another but not with the effect of taking care of the basic needs and following the ancient rules

If the angina worsens because the patient is not taught how to get well the Aesculapian assumes that the disease has got worse escalates the investigations and therapy and begins to discuss the implications of surgical treatment This approach may increase the anxiety and the relative coronary insufficiency and precipitate a breakdown—a tragedy if all the patient really needs is the removal of exhaustion and hyperarousal and the provision of good sleep to enable the demands upon the heart to fall back within the area of coronary competence[5]

An important feature of the cardiologist s map has always been iatrogenic disorder and in my opinion this has been expanded beyond belief by the beta blockers It is now commonplace to encounter the expected and reversible complications of reduced cardiac output such as cerebral vascular insufficiency intermittent claudication weakness tiredness and inability to cope with tasks and a frequent cause of consultation is the patient s inability to convince his doctor that the beta blocker is doing nothing to halt his deterioration towards a second or third myocardial infarction In some cases the doctor thought the drug effects were caused by arteriosclerotic deterioration In other cases he has recognized the noxious effects of his therapy but the propaganda has made him fear to stop it All too often the doctor was so persuaded of his drug s virtues that he closed his mind to his patients heretical reports[34]

It is time someone put on the map the belief that it might not be dangerous to stop beta blockade provided that sleep deprivation exhaustion and morbid arousal have been dealt with first[5] I regard it as essential to stop beta blockers during my preparation of a cardiac patient for training at the gymnasium Beta blockers may increase effort capacity by 25 to 50% in angina pectoris[35] which is negligible by our standards but they fail to prevent the left ventricular end diastolic pressure from rising too high with exercise[36] It is this excessive rise of pressure which increases the left ventricular wall tension creates patchy ischemia and invites arrhythmia and sudden death and which also stiffens the pulmonary venous system thereby creating unpleasant dyspnea instead of pain in some cases Furthermore beta blockade restricts the freedom of the heart rate to rise and so removes our simplest guide to the net effect of exercise fatigue and emotional arousal during cardiac rehabilitation

Coronary artery bypass grafting must have a place on the cardiologist s map because it exists so widely and profitably and because it has such a large industry growing up about it It is a pity that the evaluation has been so poor[6] because its logic is unappealing Some people generate angina get over their troubles and recover Others keep it going for years aggravate it at will and crash into infarction and sudden death almost regardless of the appearances of the coronary arteries and myocardium when they begin their careers of ill health pain and disability[3] The operation may bypass some of the debris and damage accumulated during their arteriopathic catecholamine storms but how can it teach them to survive? It is surprising how uncommonly surgical treatment is sought when a strong and humane attempt has been made to meet the basic needs and to teach the ancient rules of angina

Early diagnosis of pericarditis in acute myocardial infarction

Jaber I Sawaya M D
Salim K Mujais M D
Haroutune K Armenian M D Dr P H
Beirut Lebanon

Although pericarditis developing during the acute phase of myocardial infarction has not been shown to substantially increase the hospital mortality rate[1-6] recognition of this complication remains important in order to avoid other diagnostic possibilities including extension of the infarction and extensive myocardial damage based on the elevation of the ST segment[7]

The purpose of this study is to explore the predictive value of several factors in the patient s profile that can alert the physician to the early diagnosis of pericarditis in acute myocardial infarction The value of salicylate treatment is also assessed in these patients with a review of the literature

Materials and methods

Data on all patients admitted to the Coronary Care Unit of the American University Hospital between July 1 1977 and December 31 1978 were stored on a system 3 digital computer Two hundred and sixty one patients had unequivocal evidence of acute myocardial infarction based on at least two of the following criteria (1) typical history of prolonged coronary pain (2) evolution of ST T wave changes and abnormal Q waves and (3) significant rise in serum enzymes creatinine phosphokinase (CPK) as determined by the method of Okinaka and associates glutamic oxaloacetic transaminase (GOT) and lactic dehydrogenase (LDH) frequently with isoenz determinations Patients were continuously m itored between 3 and 5 days and on subseq days when major complications developed 12 lead electrocardiogram was recorded daily 3 days on all patients and daily thereafte pericarditis or other major complications curred A portable chest x ray was done admission and was repeated at least once du the hospital stay Serum enzymes were de mined on admission and for 3 consecutive d Subsequent determinations were done if ex sion of infarction was suspected or when peri ditis developed The patient s demographic clinical characteristics coded and stored in computer included the following age sex qu of pain on admission previous history of coro pain location of the infarction previous d mented myocardial infarction and delay admission to the hospital in hours Complicat previously established to occur in acute myo dial infarction were also identified Indivi arrhythmias are classified according to Ch and ventricular arrhythmias were graded acc ing to a modification of Lown and associat Primary ventricular fibrillation was diagn when the arrhythmia occured within 48 h from admission and secondary ventricular fi lation was diagnosed when this arrhyth occurred in the setting of pump failure afte hours Fascicular blocks were diagnosed acc ing to the criteria of Rosenbaum and colleag Heart failure was classified according to criteria of Killip and Kimball[13] Blood lipid ab malities were classified according to Frede son Other stored information included intake established coronary heart disease

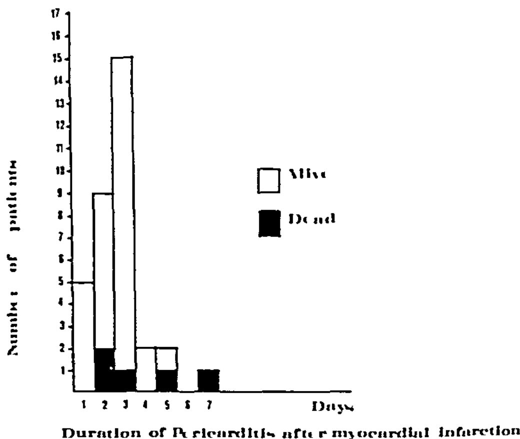

Fig 2 Duration of pericarditis after myocardial infarction

$$Y = a + b_1X_1 + b_2X_2 + \dots b_nX_n$$

Where Y is the dichotomous dependent variable indicating the presence or absence of pericarditis the b s are the regression coefficients, The X s are the independent variables, and *a* is the constant

Using such a technique it was possible to calculate for each of the variables the proportion of the variation explained by the factor under consideration

Results

Clinical characteristics and risk factors Of the 261 patients with acute myocardial infarction 38 with transmural myocardial infarction had pericarditis (14.5%) All patients were males. Some of the clinical features are shown in Table I A comparison between the pericarditis patients and their controls did not reveal any significant difference as to the character of chest pain on admission, history of previous myocardial infarction or angina, or the location of infarction A confirmatory two-component friction rub was audible in all patients this occurred between the second and fourth day from the onset of myocardial infarction pain in 33 patients In none of the patients did friction rub appear after the fifth day (Fig 1) In the majority of the patients who died the pericarditis lasted longer than 3 days (Fig 2)

Considering that the pericarditis in the patients was caused by the pathological processes related to the myocardial infarction the latent period between the onset of symptoms of myocardial infarction and the onset of pericarditis was calculated as an expression of the incubation period of pericarditis Using the method of Sartwell as applied to non infectious diseases,[a] the median incubation period and its dispersion factor were calculated for pericarditis following myocardial infarction based on our own data and on data from Lichstein and co workers[3] The estimated median incubation period was 42 hours with a dispersion factor of 1 53 Thus about 95% of the pericarditis is expected to develop between 1 and 95 hours from the onset of the myocardial infarction

Twenty nine pericarditis patients had congestive heart failure Killip s class II or above compared to 15 matched controls. This difference was statistically significant (Table II) Radiological

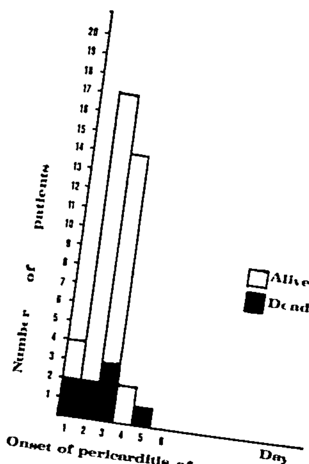

Fig 1 Onset of pericarditis after myocardial infarction

factors hospital stay in days and mortality status A detailed problem oriented medical record was constructed on each patient which permitted accurate and frequent documentation of events No postmortem studies were done

The diagnosis of pericarditis (AMI P) was made when a two component friction rub was heard by the house staff and was confirmed by at least one senior cardiologist Those who developed a friction rub after cardiopulmonary resuscitation were not included in the study Patients with pericarditis and controls were examined several times a day

Each case of pericarditis (AM P) was matched with one control of the same age and sex from the remaining 223 patients with acute myocardial infarction but with no evidence of pericarditis Thus 38 controls (AMI C_1) were selected at random either from the dates preceding or following the date of admission of the case of pericarditis

As an initial step in analyzing the data comparisons were made between the cases of pericarditis and the remaining group of acute myocardial infarction patients with no pericarditis (AMI C) in addition to the case control comparisons between AMI P and AMI C The percentage distributions of cases and controls were calculated for each characteristic and a matched pair analysis was done for the comparison of AMI P and AMI C Such comparisons were used to assess variables that could have a predictive value in identifying patients admitted to the coronary care unit who are at risk of developing pericarditis as a complication of acute myocardial infarction

In addition using the Statistical Package for the Social Sciences Program a stepwise multiple regression analysis was done In order to develop a predictive model for pericarditis in acute myocardial infarction the effect of significant independent variables was assessed in a stepwise manner adding one variable at a time Thus the predictive value of each of these variables could be assessed following adjustment for the rest of variables The model used was

Mortality Eight (21%) of the pericarditis g died in the hospital compared to 5% in matched control AMI C_1 ($P < 0.01$) The h tal mortality rate of all the myocardial infar patients without pericarditis was 17% and difference was not significant compared to pericarditis patients (Table VI)

Discussion

Pericarditis in myocardial infarction has clinically recognized to occur between 6 8% 16% in various series[1,5,7] while in an aut series 80% of patients with myocardial infar had pericardial involvement [1] This discrep might be attributed to (1) inadequate docume tion in clinical retrospective studies (2) the f ing nature of the diagnostic pericardial fric rub and (3) the lack of predictive factors alert the coronary care staff to the patient at risk of developing pericarditis

The higher incidence of pericarditis in our compared to other clinical studies (Table

evidence of congestive heart failure included pulmonary congestion (10 patients), acute lung edema (three patients), and cardiomegaly (two patients). *In addition, six pericarditis patients* had a combination of infiltrates, atelectasis, or pleural effusion. Seventeen patients had normal chest x-rays.

In six patients diffuse ST segment elevation typical of pericardial inflammation was noted at the time pericarditis was diagnosed clinically (Figs. 3 and 4). In the rest of the patients the appearance of the rub was not associated with any significant ST shifts. In patients with anterior infarction the peak ST elevation measured within 24 hours from onset was 5.9 mm for AMI-P compared to 2.8 mm in AMI-C_1 ($P < 0.01$). For patients with inferior infarction these averages were 2.9 and 2.2 mm, respectively ($P < 0.05$).

All patients with pericarditis had one or more complications of myocardial infarction, while at least one third of the controls were free of complications (Table III). Twenty-four pericarditis patients had sinus tachycardia compared to 13 of the matched controls. There was no difference in the occurrence of supraventricular or ventricular arrhythmia, atrio-ventricular or fascicular blocks. The two groups did not differ significantly as to the presence of the following risk factors: diabetes, hyperlipidemia, hypertension, smoking, positive family history of coronary heart disease, hyperuricemia, and obesity.

Laboratory results. Pericarditis patients had significantly higher mean values of peak CPK and LDH compared to the matched controls ($P < 0.05$), as shown in Table IV. SGOT peak values did not show such a difference. Six out of eight pericarditis patients who died had CPK values higher than 60, while only five of the 30 surviving had such high values of CPK ($P < 0.01$).

Multiple regression analysis. *In an effort to* assess the predictive value of these clinical and laboratory findings for pericarditis in acute myocardial infarction, a stepwise multiple regression analysis was done using the presence or absence of pericarditis as the dependent variable and the Killip's classification for congestive heart failure, the peak ST segment elevation in millimeters within 24 hours from onset, and the peak values for LDH, CPK, and SGOT as the independent variables. As illustrated in Table V, following multiple adjustment, the variable that could explain more of the variation as to the development of pericarditis was the ST segment elevation, and a significant contribution by this variable was maintained throughout the stepwise multiple regression analysis. The regression coefficients for the peak enzyme values and the Killip's classification for congestive heart failure were small and not significant and were of minimal predictive value.

Treatment. Thirty-one patients were treated with salicylates at an average dose of 2 to 3 grams per day for 10 to 14 days. Response was satisfactory in 27 patients (87%) with prompt and sustained relief of pain without complications. Follow-up at 3 weeks following discharge did not show recurrence of pericarditis or the development of postmyocardial infarction syndrome.

MI myocardial infarction

mapping studies and the standard six lead precordial electrocardiogram improves the value of the latter tool in the diagnosis of pericarditis

Sinus node and atrial irritation described by James in patients with pericarditis increase the vulnerability to supraventricular arrhythmia Arrhythmias are rather common complications in myocardial infarction Most studies unlike ours have indicated a high incidence of arrhythmia in patients with pericarditis

Our findings of increased pump dysfunction in patients with pericarditis are in agreement with previous observations This dysfunction is a reflection of increased myocardial damage in these patients manifested by the pericardial involvement The appearance of the pericardial rub within a few hours from the onset of myocardial infarction probably carries a grave prognosis

It is important to note that in the multiple linear regression analysis the variable that could explain more of the variation as to the development of pericarditis was the ST segment elevation The finding that the extent of CPK LDH and SGOT elevation and degree of pump dysfunction did not contribute significantly to explain the variation in this model may be due to the fact that ST segment elevation has measured the same myocardial changes that are expressed by enzyme elevations and pump dysfunction Thus, ST segment elevation in itself is possibly a better clinical indicator of these changes under these circumstances Only 35% of the variation could be explained between pericarditis patients and their controls using the above mentioned variables Further studies need to be done to investigate the possible role of other variables and indicators in this condition

Summary

Pericarditis complicating acute myocardial infarction assumes increasing importance in this era of quantitating infarct size by precordial ST segment mapping Early recognition of this complication avoids diagnostic and therapeutic errors In this study we looked for factors that could alert to the early diagnosis of pericarditis such as ST elevation measured within 24 hours from onset extent of CPK LDH and SGOT elevation as well as degree of pump dysfunction ST segment elevation in millimeters on admission seemed to be one factor that was of predictive value in this condition

Pericarditis occurred in three forms (1) within a few hours from the onset of myocardial infarction and this form seems to carry a high mortality rate (2) a more common variety occurs within 24 to 72 hours from onset and carries a higher mortality rate than matched controls and (3) the late syndrome of Dressler s not observed in our series Aside from increased incidence of heart failure other complications of myocardial infarction and the coronary risk factors were not significantly higher in patients with pericarditis Salicylate treatment offers immediate relief in the majority of patients

correlated with the magnitude of ST segment elevation [25] Lichestein[5] reported more marked ST segment shifts in their patients with pericarditis Hardarson and co workers [6] and Zmyslinski and colleagues noted a secondary rise of persistent ST elevation in the patients who developed pericarditis studied by precordial mapping The good correlation demonstrated between precordial ST

Evaluation of the anatomy of congenitally malformed aortic valves by orifice view aortography

Gordon M Folger Jr MD *
Hani N Sabbah BS
Paul D Stein MD
Detroit Mich

Employing a cineaortographic technique whereby the patient is rotated so as to cause en face viewing of the aortic valve[1,2] it is possible to determine aortic valve area accurately This technique of orifice view aortography is particularly useful in children where the assessment of aortic stenosis often necessary prior to the development of symptoms is at times difficult and occasionally not possible by conventional means[3] Of considerable importance in such individuals may be knowledge of aortic valve anatomy especially as it pertains to operability by simple valvular commissurotomy as opposed to aortic valve replacement

This study presents the results of a critical review of our experience using this technique with congenital aortic valvular malformations in regards to the ability to delineate accurately the appearance of the aortic valve

Materials and methods

Nineteen patients with clinical findings indicative of congenital aortic valve malformations were studied The age of the patients ranged from 11 to 36 years average 19 years The technique and method of photographing the aortic valve en face has been previously described in detail[1] and the technique for positioning the U arm angiographic system to achieve this view has also been described Briefly the patient is positioned on the angiographic table in the direct right lateral projection and the table is angulated 35 to 40 degrees off the vertical causing the x ray beam to travel essentially from the right axilla to the left iliac crest Aortography is then performed with a standard catheterization technique the tip of the catheter being positioned in either sinus of Valsalva The aortic valve is thus viewed as though looking into the aorta as it exits the heart The orientation of the valve on the film is such that the right and left aspects are respectively to the viewer s right and left the superior and inferior aspects respectively represent the anatomic anterior and posterior aspects[1]

The congenitally abnormal aortic valves were all viewed in this manner and were analyzed for configuration including the number of commissures and thus the number of functioning leaflets the appearance and position of each leaflet the presence or absence of an identifiable leaflet raphe the appearance and position of the valve orifice and the number as well as sinus of origin of the coronary arteries Each was also analyzed for the presence of aortic regurgitation without consideration to degree In addition the area of each valve leaflet was planimetered and expressed as a ratio of the larger to the smaller leaflet regardless of their relative positions

Thirteen patients had clinical and hemodynamic evidence of congenital valvular aortic stenosis with or without associated regurgitation as their only identifiable abnormality The remaining six patients had other associated malformations of the heart including four individuals with coarctation of the aorta and one each with fixed

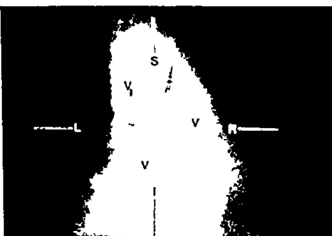

Fig 1 Orifice view of normal aortic valve Quadrant markers S I R and L indicate superior inferior right and left aspects of angiogram as viewed in this and all subsequent illustrations All three sinuses of Valsalva (V_l = left V_r = right V = non-coronary) are clearly seen densely opacified surrounding the triangular appearing orifice and separated from each other by their respective commissures

Table II Classification and findings

Group 1	Two unequal leaflet	
a	Larger leaflet inferior	
	to right	2 cases
	to left	3 cases
b	Larger leaflet superior	
	to left	3 cases
Group 2	Two equal leaflets	
a	Supero-inferior orientation	4 cases
b	Right left orientation	1 case

ration The Group 2 patients (Figs 2 and 5) to the contrary were clearly bicommissural and anatomically and functionally bicuspid An identifiable notch or indentation of a leaflet which we interpret as a raphe was present only in the Group 1a valves (Fig 3) and was uniformly present in the dominant leaflet appearing as a rudimentary separation of this leaflet into the right and non coronary components This raphe is to be distinguished from the commissural fusion resulting in the unicommissural appearance described above

The planimeterized leaflet areas further allowed grouping as described above The ratio of the dominant to non dominant leaflet in all Group 1 valves exceeded 2 1 and was less than 3 1 The Group 2 ratio never exceeded 1 6 1

The orifice appearance was determined by valvular configuration Thus all Group 1 valves exhibited eccentric positions of the orifice Group 1a cases having a superior and generally leftward position (Fig 3) and the Group 1b cases having an inferior and either slight rightward or leftward orientation (Fig 4) The Group 1b valves also appeared to have more complete development of each commissure thus appearing more like the Group 2 valves in this respect and this type of bicuspidization has been indicated by Edwards The Group 2 valves however all had centrally located orifices Group 2a (Fig 2) having a generally horizontal orientation and Group 2b a vertical orientation (Fig 5)

The 13 patients having aortic stenosis unaccompanied by other anomalies comprise all of Group 1 and as well five cases from Group 2 Thus the remaining cases all having additional anomalies had equally bicuspid valves with the exception of the individual with an unequally tricuspid valve

Aortic regurgitation

Aortic regurgitation mild in all instances occurred in four patients in Group 1 whereas only two patients in Group 2 revealed aortic regurgitation one of these patients also had subvalvular aortic stenosis a lesion commonly associated with valvular regurgitation and the other had significant calcific aortic valvular deposits The individual with unequal tricuspid aortic valvular anomaly also exhibited regurgitation

Coronary arterial pattern

The origins of the coronary arteries could be identified in 18 of the orifice view aortograms and a definite pattern could be established in regard to the various valvular configurations Thus in each of the Group 1a valves (Fig 3) the coronary arterial origin appeared essentially normal, the left coronary artery arising from the superior and leftward sinus the right from the rightward aspect of the dominant inferior sinus always to the right of the leaflet raphe This pattern appeared to indicate that the raphe indeed demarcates the absent commissure between the right and non coronary leaflets This pattern of coronary origin did not occur in any of the other valves in the other groups although one of the Group 1b valves had a similar appearance the right coronary artery arising from the right lateral aspect of the sinus of the inferior and non dominant cusp near the commissure and the left coronary ostium appearing at the left lateral

Table I Summary of aortic valve findings

Group	No of patients	Range of peak aortic gradient (average)	Spatial orientation of leaflets[a] (cases)	Leaflet size ratio dominant/non dominant	Raphe position in dominant leaflet	Number and sinus of origin of coronary arteries (cases)	A.R	Orifice location	Other cardiac defects	Surgery

Refers to spatial orientation not anatomical configuration

subvalvular aortic stenosis and double outlet right ventricle Four patients have been submitted for surgery one having aortic valvular commissurotomy and three having valve replacement The appearance of the valve in these individuals is available for comparison with the appearance on the orifice view aortogram

Results (Table I)

The appearance of the normal aortic valve on *orifice view aortography is pictured (Fig 1) for* orientation As viewed in this projection the non coronary leaflet occupies the most inferior position with the left coronary leaflet appearing superior and somewhat leftward and the right coronary leaflet appearing somewhat inferior and principally rightward The structure of the congenitally malformed valves was readily evaluated due in part to their tendency to produce a domed appearance during systole This dome seen as a moderately lucent area surrounding the more lucent and often nearly radionegative orifice provided very satisfactory visualization of the *leaflets (Fig 2) and allowed* their measurement by planimetry following image magnification with projection of the selected cine frames

Gross appearance (Table II)

The congenitally malformed values with one exception could be grouped according to gross appearance either as having two leaflets markedly disparate in size (Group 1) or two essentially equal sized leaflets (Group 2) Additionally each group could be subdivided depending upon the spatial orientation of the leaflets Group 1a had the configuration in which the larger (dominant) leaflet was inferior to the smaller (non-dominant) leaflet oriented somewhat to the right in two cases and to the left in three (Fig 3) whereas the three cases comprising Group 1b (Fig 4) had the *dominant leaflet superior and to the left of the* non dominant leaflet Group 2a (Fig 2) exhibited a principally superior inferior leaflet orientation (nine cases) and Group 2b revealed right left orientation (one case) (Fig 5) The sole exception to this classification was a patient having the additional abnormality of double outlet right ventricle in whom the aortic valve was unequally tricuspid with essentially normal leaflet orientation

The Group 1a valves (Fig 3) were all unicommissural Each had one short commissure which allowed partial leaflet separation with systole The other commissure was fused from valve orifice to periphery Thus valves of this type may also be considered as functionally unicuspid although two leaflets are identifiable Those in Group 1b (Fig 4) although similar appeared to have better development of each commissure and thus all tended toward a bicommissural configu

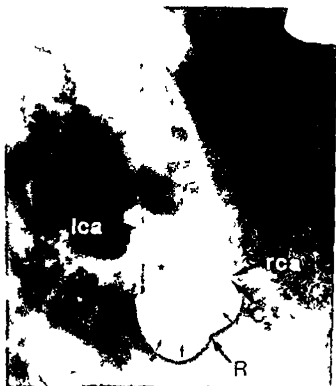

Fig 3 Orifice view of Type Ia valve Peak systolic gradient 47 mm Hg The orifice is marked by asterisk and occupies an eccentric position leftward and superior in the valve incidentally demarcating the superior aspect of the valve dome the inferior margin demarcated by small arrows One commissure (C_1) clearly opens into the orifice the other (C_2) is fused for some distance The two leaflets are obviously of different sizes the dominant inferior leaflet revealing an indentation representing a raphe (arrow R) Left coronary artery (lca) arises from the superior sinus and right coronary artery (rca) from rightward aspect of the inferior sinus This valve is considered a type amenable to simple commissurotomy in view of the long fused commissure

cannot be satisfactorily calculated hemodynamically and a reliable adjunctive measurement in the presence of satisfactory data obtained at the time of left heart catheterization During collection of this data it has become apparent that the technique also allows acquisition of information concerning aortic valvular anatomy in addition to orifice size which may have bearing on the method of surgical management

The aortic valvular anatomic findings by orifice view aortography although similar are not identical to the gross anatomic features reported by Roberts A greater percentage of valves seen angiographically had the appearance of being essentially unicommissural Thus all of the valves included in Group Ia and one from Group Ib had such a configuration comprising 38% of the total excluding the single example of stenotic tricuspid valve Roberts reported a somewhat smaller percentage (20%) of this valve type This difference however may be explained by the fact that most of our patients were children or young adults and this form of aortic valvular malformation has been considered to be the only type inherently stenotic as well as obstructive at birth It should be noted however that four of our patients with no additional cardiovascular malformations had equally bicuspid aortic valves two requiring surgery as adolescents suggesting possible significant stenosis from infancy contrasting somewhat with the report by Edwards that such valves became stenotic principally with the aging process Although each of these valves was essentially without commissural fusion they did not appear to exhibit angiographically the dysplastic appearance reported in this type of valve as a cause of obstruction by Cheitlin and associates[11] and such was also the case in two valves at the time of surgical excision The other five patients had associated malformations and all had trivial or absent aortic valve gradient

Clear cut evidence of a leaflet raphe could be observed angiographically only in those valves representative of Group Ia in which the dominant leaflet appeared to represent fusion of the right and non coronary leaflets although Roberts occasionally found raphes in either or both leaflets regardless of anatomical appearance

Similarly the coronary arterial patterns observed angiographically vary from the findings of Roberts in respect to the Group I cases but are identical in respect to those in Group 2

With these differences from the reported anatomic valvular appearance taken into consideration it seems apparent that orifice view aortography is useful in delineating the anatomy of the malformed aortic valve In four of our patients so far it has quite reliably predicted the anatomy discovered at surgery At present attention is being concentrated upon the appearance of the commissures as regards the presence or absence of identifiable fusion and extent of fusion

The importance of a technique allowing determination of aortic valvular anatomy prior to aortic valve surgery is greatest in childhood and early adult life principally as regards identification of valves amenable to commissurotomy as

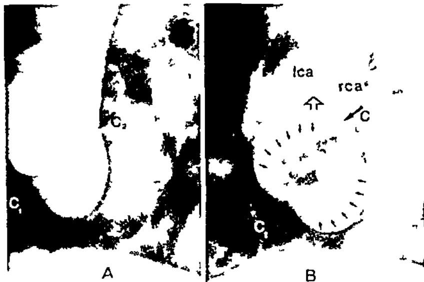

Fig 2 Orifice view of bicuspid aortic valve of Type 2a illustrating features of bicuspidization (see text for description) Peak systolic gradient = 12 mm Hg Coarctation of aorta is associated malformation *A* Valve closed The two commissures are designated by arrows C_1 and C_2 and line of leaflet coaptation may be seen extending from C *B* Valve open The commissures are again identified by arrows C C. The valve orifice presents an elliptical appearance (lucent center) surrounded by a "halo" of lesser lucency (*small arrows*) which represents the valve dome The coronary arteries (*rca* = right *lca* = left) are seen to arise from a single vessel (single left coronary artery) from the superior sinus of Valsalva (*open arrow*)

aspect of the sinus of the dominant cusp The other Group 1b valve revealed both coronary arteries to arise from a single ostium and a trunk located at the right lateral margin of the sinus of the superior dominant leaflet One Group 1b valve could not be analyzed for coronary origin Somewhat similarly (Fig 2) seven of the Group 2a valves had single origin of both coronary arteries from the sinus of the superior cusp and two exhibited the right and left coronary arteries arising separately also from the sinus of the superior cusp The single example of Group 2b had the origin of the right coronary artery from the sinus of the rightward cusp and the left coronary from the sinus of the leftward cusp Finally the individual with unequal tricuspid aortic valve had single origin of both coronary arteries from the sinus of the anatomic right cusp

Anatomic correlation

One patient underwent simple aortic commissurotomy and is the only individual in this series representing Group 1a The angiographic appearance of the valve in this patient indicated a commissure fused for sufficient length to allow for this type of operation At surgery this finding was confirmed and incision was carried out without difficulty The postoperative residual gradient across the aortic valve was 20 mm Hg reduced from 60 mm Hg preoperatively One individual representing Group 1b with angiographic evidence of a nearly continuous slit like orifice without apparent significant commissural fusion required valve replacement Likewise two examples of valves having Group 2a configuration with virtually no commissural fusion also required valve replacement Each of these valves were available in nearly a complete form after surgical removal and each had an appearance similar to the angiographic (Fig 6)

Discussion

The technique of orifice view aortography has been previously shown to be a method by which the size of the aortic orifice could be calculated [2] We have recently demonstrated excellent correlation of the aortic valve area measured by orifice view aortography with that calculated by hydraulic equation concentrating on young individuals with congenital malformations of the aortic valve The sensitivity of the technique is sufficient to allow it to be considered a definitive study for this parameter if for any reason the area

Fig 6 Orifice view of aortic valve Type 2a in *left panel* and appearance of valve at surgical removal, oriented similarly in *right panel* Peak systolic gradient = 102 mm Hg Dome defined by *small arrows* with orifice appearing densely lucent within it Commissures (*arrows* C_1, C_2) fused for short distance Note similar appearance of surgical specimen Commissures were not fused for sufficient length to allow adequate surgical relief as indicated by aortic angiogram

opposed to those requiring replacement If fusion of one or both commissures is observed it is likely that commissurotomy could be performed and provide satisfactory relief of the stenosis The valves with Group 1a configuration stand out prominently in this respect On the other hand if the orifice view aortogram shows that there is little or no fusion of the commissures it is apparent that commissurotomy would not provide satisfactory relief of stenosis and valve replacement would be necessary Avoidance of prosthetic valves all types of which currently in use are fraught with the disadvantage of early failure in the essentially symptom free young patient is preferable to exposing these individuals to the risk of multiple valve replacement and excepting the porcine xenograft the potential risk of thromboembolism Viewing the aortic valve by orifice view projection appears to allow such identification

Summary

Nineteen patients with congenital abnormalities of the aortic valve were studied by orifice view aortography and the anatomic configuration of each valve was determined With one exception all valves were bicuspid The bicuspid aortic valves could be grouped into two distinct categories Group 1 valves had unequal leaflet size and could be further subgrouped depending upon the spatial orientation of the leaflets The commiss ral structure of this type of valve was such th with but two exceptions valvular configurati appeared essentially unicommissural The valv comprising Group 2 exhibited essentially equ sized leaflets and thus are considered equal bicuspid These valves displayed a central orie tation of the orifice and thus are bicommissural contrast to the unicommissural Group 1 valv which all had eccentric orifice position The aort valves examined by this technique exhibited clo similarity to descriptions of valves at the time pathological examination

Orifice view aortography appears to be a repr ducible method of determining the anatomy the aortic valve which can be applied as a preop erative evaluation useful in determining whethe relief of aortic stenosis by aortic commissurotom as opposed to valve replacement is feasible Fou patients undergoing aortic valve surgery on with commissurotomy and three with valv replacement have revealed findings at the time o operation confirmatory of the anatomical config uration of the valve predicted by orifice view aortography

The clinical importance of cardioselectivity and lipophilicity in beta blockers

John M Cruickshank DM MRCP*
Macclesfield Cheshire and Manchester England

Ever since Lands in 1967 proposed the existence of two types of beta receptor—beta 1 and beta 2—it has been theoretically desirable for a beta blocker to possess the property of cardioselectivity i e to preferentially block in a competitive fashion the cardiac beta 1 receptor leaving the peripheral beta 2 receptors relatively unhindered A beta blocking agent which is non selective might be expected to confer all the benefits of beta 1 blockade (Table I) but possibly be harmful in blocking beta 2 receptors in for instance (a) bronchial muscle causing bronchoconstriction (b) blood vessels causing vasoconstriction or (c) the liver and muscle prolonging hypoglycemia

Another property of beta blockers the partition coefficient in octanol and water has recently gained prominence A high partition coefficient is associated with lipophilicity and a low coefficient with hydrophilicity Lipophilic beta blockers in general (a) tend to be metabolized by the liver and (b) reach all compartments of the body with relative ease Hydrophilic beta blockers tend (a) to be non metabolized and excreted unchanged by the kidney and (b) reach the deeper compartments of the body such as the brain with relative difficulty

The properties of a beta blocker in particular the properties of cardioselectivity and lipophilici-

ty can be predicted from its molecular structure Beta blockers possess either an ethanolamine or an oxypropanolamine side chain (Fig 1) the latter generally conferring greater potency The first beta blockers dichloroisoprenaline (DCI) pronethalol and propranolol (Inderal)* Fig 1 were non selective Subsequently cardioselective oxypropanolamine beta blockers (Fig 2A) were developed which had the common structural feature of an amidic (practolol—Eraldin atenolol—Tenormin acebutolol—Sectral) or other hydrogen binding function (metoprolol—Lopressor or Betaloc) in the paraposition of the benzene ring The amidic functions in particular also reduce the lipophilicity of the molecules Thus atenolol for example is both cardioselective and has low lipophilicity (hydrophilic) That cardioselectivity and hydrophilicity do not necessarily go hand in hand though is shown by the examples of Fig 2B

Beta blockers as a group of drugs are relative to other types of antihypertensive and antiangi-

does not change after chronic administration [1,12] Lipophilic beta blockers by contrast tend to have short plasma half lives The half life of propranolol after a single dose is 2 to 3 hours but appears to lengthen a little after chronic administration [1] This fact is due probably to saturation of the liver enzyme system responsible for the metabolism of propranolol

Clinical implications The possible clinical implications of the above facts are in the areas of dosage interval and predictability of action The former is dealt with later The small between patient variation in peak blood levels of a hydrophilic drug such as atenolol affords a certain predictability of action which is reflected in the narrow dose range for both hypertension and angina [14,15] This contrasts with the large var tion in peak blood levels of the lipophilic li metabolized beta blockers [1] necessitating in vidualisation of dosage However even propra lol might well have a much narrower dose ran than was suggested by earlier studies [17]

2 **Distribution** Within the plasma be blockers bind to proteins in varying degrees T degree of protein binding appears to be indepe dent of the partition coefficient Thus a hyd philic compound such as atenolol is poorly pr tein bound at about 3% [18] Propranolol which highly lipophilic is about 90% protein bound[1] however metoprolol which is also lipophilic only 10% protein bound [2] Now the volume distribution of beta blockers through the vario

nal agents effective and cause few troublesome side effects So in practical terms how real are the supposed advantages of cardioselectivity and how relevant is the property of hydrophilicity? The examples used in this paper for cardioselective agents are atenolol and metoprolol and for the non cardioselective agents propranolol (though not exclusively) The representative of the hydrophilic group of beta blockers (practolol atenolol sotalol and nadolol) will in the main be atenolol and of the lipophilic beta blockers propranolol and metoprolol The subject will fall under two main headings

1. Pharmacokinetics highlighting important differences between hydrophilic and lipophilic beta blockers and the clinical implications, and
2. Pharmacodynamics of cardioselective and non selective beta blockers and the clinical implications

Fig 2A Cardioselective beta blockers partition coefficient in octanol/water and structure

Pharmacokinetics—contrasting hydrophilic and lipophilic beta blockers

1 Absorption Hydrophilic drugs have difficulty in crossing cellular membranes and tend to be poorly absorbed from the gut Thus approximately 50% of atenolol[1] and 30% of nadolol are absorbed from the gut However in the case of atenolol at least at a given dose peak blood levels are relatively constant and predictable varying only three to fourfold between patients[3,5] In contrast lipophilic beta blockers such as propranolol[6,7] and metoprolol[8] are well absorbed though there is some twentyfold variation in peak blood levels This variability of peak blood levels is presumably due to the fact that these drugs are metabolized by the liver

Hydrophilic beta blockers tend to have long plasma half lives For example the half life of atenolol after a single dose is 6 to 9 hours[10,11] and

dence of adverse reactions relating to the CNS such as psychosis depression hallucinations nightmares and insomnia [6] Psychotic problems and other CNS side effects arising with lipophilic beta blockers which enter the brain in high concentration[2, 2] disappear or markedly improve when a hydrophilic beta blocker is substituted [9 31] Sixty three such patients suffering CNS side effects on lipid soluble beta blockers were changed to atenolol in 92% the CNS side effects either disappeared or were markedly diminished [30]

3 Excretion Hydrophilic beta blockers tend to be poorly metabolized Thus atenolol is excreted almost totally unchanged by the kidney Ninety to 95% can be recovered in the urine within 48 hours of intravenous administration [1] A small amount 5 to 10% is metabolized by the liver to form a hydroxy metabolite and a glucuronide both of which have only weak pharmacological action [3] In the case of lipophilic beta blockers such as propranolol alprenolol metoprolol and oxprenolol some of the orally administered drug fails to reach the systemic circulation because the drug in the portal vein is taken up and removed by the liver This is termed the first pass effect These drugs are almost wholly metabolized by the liver [33 34] forming metabolites which are weakly pharmacologically active

The plasma half life of a hydrophilic drug like atenolol lengthens with kidney dysfunction,[35] with half lives of 50 hours in patients with very severe dysfunction (glomerular filtration rate 0 to 10 ml /minute) However at glomerular filtration rates) (GFRs) greater than about 35 ml /minute or a serum creatinine less than 2 5 mg % or 300 mmol /L there is no significant accumulation of the drug in the blood [36 3] Lipophilic beta blockers when given to patients with renal failure theoretically should not accumulate However hepatic function and with it the first pass effect appears to be impaired in patients with severe renal failure so that even lipophilic beta blockers like propranolol and metoprolol appear at substantially higher peak blood levels than in patients with normal renal function [34 35] There is also a marked accumulation of metabolites at this time

Elderly (70 years+) compared to young subjects have a decrease (about 40%) in both renal[1] and hepatic function As a drug such as atenolol is virtually unmetabolized by the liver and does not accumulate significantly at GFRs greater than about 35 ml /minute the aging effects upon the kidney and liver should be of little consequence Indeed it has been shown that the pharmacokinetics of a hydrophilic beta blocker (practolol) are similar in both the young and elderly[37] In the elderly liver metabolism of a lipophilic agent such as propranolol is impaired so that blood levels of the parent drug are increased some fourfold with chronic dosing in the elderly [4] With metoprolol there is pronounced inter individual variation in peak plasma levels in the elderly [3]

Clinical implications

a RENAL FAILURE Patients with normal or mild renal dysfunction (GFR greater than about 35 ml /minute or a serum creatinine of less than 2 5 mg % or < 300 mmol /L) do not accumulate (to a significant degree) hydrophilic beta blockers such as atenolol [6 3] thus a normal dosing regimen may be recommended Patients with moderate (GFR 10 to 35 ml /minute or serum creatinine between 2 5 and 5 0 mg % or 300 to 600 mmol /L) and severe (GFR < 10 ml /minute or serum creatinine > 5 0 mg % or > 600 mmol /L) renal dysfunction do accumulate atenolol with blood levels plateauing out in severe cases at about 2 to

Table II Concentration of beta blockers (chronic oral administration) in plasma cerebrospinal fluid (CSF) and brain—in man†

Beta blocker (BB) (dose)	No	Plasma conc ng/ml		CSF conc ng/ml		Brain conc ng/g		Mean plasma/CSF ratio	Mean brain/plasma ratio	Mean brain/CSF ratio
		Indiv values	Mean value	Indiv values	Mean value	Indiv values	Mean value

body compartments[9] depends upon both lipophilicity and plasma protein binding Thus metoprolol being moderately lipophilic and poorly protein bound has a large volume of distribution = 5 6 L/kg propranolol though having a high lipophilicity is highly protein bound and has a volume of distribution of 3 6 L/kg atenolol although being lowly protein bound is highly hydrophilic and thus has a very low volume of distribution at 0 7 L/kg

Of particular note is the very low concentration of hydrophilic atenolol in the central nervous system (CNS) in rat cat and man[14] This is in contrast to both the lipid soluble propranolol and metoprolol[2, 3] (see Table II and Figs 2*A* and 2*B*) It should be noted that the concentration of the beta blockers in the cerebrospinal fluid (CSF) is a poor predictor of brain concentration

Beta blockers are distributed within the blood/CSF/brain compartments according to the model in Fig 3 Thus in Table II the very low CSF levels of propranolol and metoprolol correspond to the approximate 10% and 90% respectively of free drug in the plasma The very high brain concentration of both propranolol and metoprolol (about 20 times higher than that of atenolol) reflects the high affinity of the brain for these lipophilic agents Early results indicate that oxprenolol another lipophilic beta blocker also appears at higher concentration in brain tissue Distribution of the lipophilic beta blockers within the blood/CSF/brain compartments occurs within *minutes* *In contrast hydrophilic atenolol* crosses the blood brain barrier with difficulty and *equilibration occurs more slowly (Fig 4)* *As the* CSF in man is completely changed about every 10 hours atenolol s concentration may be kept low by means of a continual washout or sink effect[2] Indeed the CSF and brain concentrations seem to settle at about one fifth to one tenth of peak blood values (which occur 2 to 4 hours post dosing) Thus unlike the situation with lipophilic beta blockers with atenolol the brain appears to *be buffered against peak plasma levels*

Another point of interest is the distribution of various beta blockers in lung tissue relative to blood[5] Table III shows a list of lung/blood concentration ratios with lipid soluble drugs appearing in high and highly water soluble drugs in low concentrations in lung tissue The authors offer a possible explanation of cardioselectivity with the water soluble agent (in contrast to the lipid soluble agent) *never attaining a high concentration* in the vicinity of the beta 2 receptor However on this basis sotalol and nadolol would also be selective which is not the case

Clinical implications

a PREDICTABILITY OF ACTION A drug which is poorly protein bound will not be affected by either disease states which alter plasma protein concentrations and ratios or by other drugs which may compete *for protein binding sites* This should contribute to such a drug s predictability in the clinic

b CNS SIDE EFFECTS The low concentration of a hydrophilic drug in the brain relative to lipophilic agents possibly explains the low inci

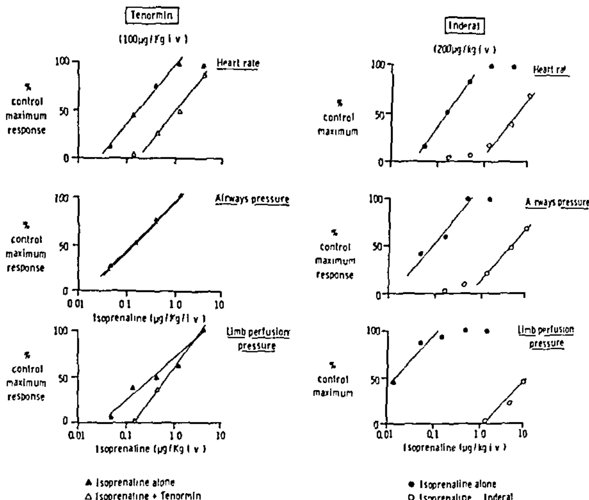

Fig 5 Effect of propranolol and atenolol on heart rate (beta 1) airways pressure (beta 2) and limb perfusion pressure changes resulting from increasing isoprenaline dosage

tions occurring in severe renal failure the cumulative beta blocking effect will be substantial This is a further possible reason for reducing the dose of lipophilic liver metabolized beta blockers in severe renal failure

b THE ELDERLY Compatible with the fact that the pharmacokinetics of hydrophilic beta blockers are similar in the young and the elderly is the observation that the incidence of side effects was the same in young middle and old age groups[45] In contrast lipophilic agents have been reported to produce side effects at a higher incidence in the elderly as compared to the young[4]

Pharmacodynamics

Beta 1 blockade

1 *Cardiovascular*

a HEMODYNAMICS All cardiac beta blockers by definition competitively block beta 1 receptors in the heart with the result that there is a slowing of the heart rate and a decrease in contractility Beta blockade is best demonstrated at the high heart rates associated with moderate to severe exercise as resting heart rates are influenced by vagal tone As stroke volume tends to remain unchanged or possibly slightly increased there is a fall in cardiac output of about 20% at maximal beta blockade The possession of intrinsic sympathomimetic activity (ISA) will tend to be associated with higher heart rates and a lesser fall in cardiac output[47] The fall in cardiac output is initially not accompanied by a fall in blood pressure owing to an alpha mediated reflex increase in peripheral resistance[48] Later probably after only 2 to 3 hours the peripheral resistance falls and is accompanied by a decrease in blood pressure Subjects whose blood pressure does not eventually fall still maintain the initial beta blocker induced increase in peripheral resistance These hemodynamic changes persist for at least one year after starting the beta blocker therapy (atenolol)[5]

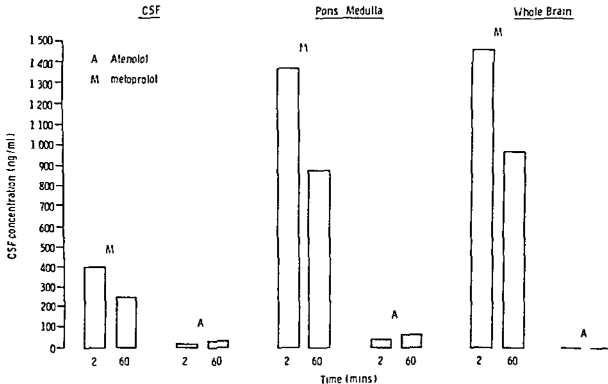

Fig 4 Cerebrospinal fluid/brain concentrations of atenolol and metoprolol Anesthetized cats drugs given intravenouslv/mg /kg

4 weeks[3] Although patients with moderate or severe renal failure tolerate the high blood concentration of atenolol perfectly well blood levels similar to those in the normal therapeutic range are desirable particularly if the benefits of cardioselectivity (which are dose related) are to be retained The conclusions of recent studies on hydrophilic atenolol and renal dysfunction indicated that normal blood levels could be obtained in patients with renal failure and that (1) patients with a GFR of greater than 35 ml/minute should have the normal dose (2) patients with a GFR of 10 to 35 ml/minute should have half the normal dose or the whole dose on alternate days (3) patients with a GFR < 10 ml/minute should have half the normal dose on alternate days and (4) patients on hemodialysis 2 to 3 times a week should be given half the normal daily dose after every hemodialysis (under hospital supervision since marked falls in blood pressure can occur)

Because hepatic function appears to be somewhat impaired in patients with severe renal dysfunction lipophilic beta blockers (propranolol and metoprolol) should also be given in reduced dosage[3] [3] in such cases With the lipophilic beta blockers there is also a marked increase in plasma concentration of liver metabolites[3,9] [0] Although these metabolites have only weak pharmacological activity it seems likely that at the concentra

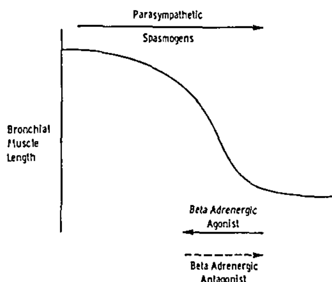

Fig 6 Dose response curve of bronchial muscle

of beta 2 receptors generally has *potentially* detrimental effects It is in these situations that a cardioselective beta blocker might be considered preferable to a non cardioselective beta blocker

Beta 2 blockade

I *Bronchus* Ideally claims for cardioselectivity should be based on data showing that the beta blocker inhibits the beta 1 effects of an agonist upon the heart while having little or no effect upon peripheral beta 2 effects—e g bronchodilation or vasodilatation Such circumstances pertained in the dog model shown in Fig 5 where propranolol produced both beta 1 and beta 2 blockade by shifting the isoprenaline/heart rate and airways pressure dose response curves to the right while atenolol modified only the beta 1 effects Metoprolol behaves in a similar fashion to atenolol[6] Harms using in vitro and in vivo models has presented a table of cardioselective indices (see Table IV) This table is in roughly the reverse order of Hemsworth s table of lung/blood concentration ratios (Table III)

Tattersfield and associates have devised a model in normal volunteers whereby beta 2 specificity or lack of it may be estimated The volunteers were given increasing doses of an inhaled beta 2 stimulant (salbutamol) and the effect upon airways conductance was measured in a whole body plethysmograph All subjects were later exposed to various beta blockers at two dose levels The doses of the various agents were chosen at levels thought to be approximately equipotent and clinically relevant Two hours after administration of the beta blocker the subjects were given salbutamol in increasing doses the effect again being measured in the whole body plethysmograph Dose ratios were estimated the dose ratio being that dose of salbutamol required to produce 50% maximum response (increase in airways conductance) for each drug and dividing this by the dose required to procude 50% response on placebo Table V shows dose ratios and it can be seen that atenolol and practolol caused the least interference with the salbutamol dose response curves and propranolol the most interference Cardioselectivity was illustrated in the case of atenolol by the fact that it caused the greatest fall in exercise heart rate (beta 1) but with practolol the least interference with airways conductance (beta 2) It can be seen that the higher the dose of a beta blocker the more of a beta 2 stimulant (salbutamol) is required to overcome the detrimental effects on airways conductance This confirms that the benefits of cardioselectivity tend to be lost at higher doses[7]

Clinical implications Work by Benson and colleagues[13 14] (Fig 6) has shown that bronchi which are not dependent upon sympathetic drive to maintain their caliber will be little affected by potential spasmogens e g beta 2 blockade Thus results of studies carried out on normal subjects whose bronchi are unstimulated must be regarded as potentially misleading Indeed it is likely that asthmatic subjects who are well with a normal or approaching normal FEV_1 (forced expiratory volume) are able to tolerate beta 2 blockade[15] However patients whose bronchi are dependent upon sympathetic tone to maintain their caliber—i e who fall on the steep part of Benson s dose response curve—are at definite risk from beta 2 blockade A study in a group of such patients[16] (Fig 7) demonstrated two important facts Under circumstances where seven different orally administered beta blockers at clinically relevant doses had produced approximately the same amount of beta 1 blockade (suppression of standing pulse rate and inhibition of the effect of isoprenaline upon the pulse rate) (1) a relatively highly cardioselective beta blocker was *least likely* to cause important branchoconstriction and (2) such a beta blocker (in contrast to non selective agents) almost completely preserved the

) BIOLOGICAL HALF LIFE Hydrophilic mainly ally excreted beta blockers tend to have long sma or chemical half lives On the other nd lipophilic mainly liver metabolized beta ckers tend to have short plasma half lives The sma or chemical half life is independent of se contrasting with the biological or pharma ogical half life which is dose dependent For mple a beta blocker such as atenolol with a g chemical half life (6 to 9 hours) when ministered in a relatively low dose of 50 mg e rise to beta blockade 24 hours after the dose ich was about 30% of maximum (decrease in art rate three hours after the dose) By doub g the dose it was possible to achieve about 70% maximum blockade 24 hours after the dose

e same principle applies to the beta blockers h short chemical half lives However if biolog l effect is required over a 24 hour period an ent with a short chemical half life will need to administered at high dosage relative to an ent with a long chemical half life even though th agents might be equipotent milligram for lligram in producing maximal beta blockade at 2 to 3 hours post dose For example metopro with a short chemical half life and atenolol h a longer chemical half life are considered to equipotent milligram for milligram in sup essing exercise heart rate or systolic blood ssure 2 to 3 hours after dosing Whereas enolol (dose 100 mg) produced a substantial crease in both exercise heart rate and systolic ood pressure 24 hours post dosing little or no ect remained 12 to 24 hours after the same dose metoprolol[5 5] However equipotency of effect er 24 hours could be achieved either by tripling e single dose of metoprolol or by giving the dose ice daily[5]

c ELECTROPHYSIOLOGY Both cardioselective enolol and non selective propranolol have the me effect on the sinus and AV nodes Both ugs equally slow the sinus rate prolong sinoa ial and AV nodal conduction time (A H in His ndle ECG) and prolong the effective refractory period of the A V node[56 5] neither the conduction time within the atrium the His Bundle and ventricle nor the refractory periods of these compartments are altered by atenolol or propranolol However one study indicated that atenolol but not propranolol increased atrail refractoriness[5]

2 *Renin* Renin release is probably primarily a beta 1 effect thus both cardioselective and non cardioselective beta blockers equally suppress plasma renin activity (PRA)[1 5 59] Earlier claims that atenolol had no effect on the renin angiotensin system[6] results from measurements on plasma renin concentration (not PRA) which was not affected by atenolol

3 *Intraocular pressure* A decrease in production of aqueous humor arises after beta 1 blockade[1] Thus both non selective and cardioselective beta blockers lower intraocular pressure with equal facility

4 *Anxiety/tremor* The peripheral signs of both anxiety and thyrotoxicosis[65] seem to be blocked equally well by both non selective propranolol and cardioselective atenolol

Clinical implications Clinical states which benefit primarily from blockade of beta 1 receptors such as angina dysrhythmias glaucoma high renin situations and possibly anxiety and thyrotoxicosis will be equally affected by both cardioselective and non cardioselective agents In hypertension and indeed angina it should be possible to administer a hydrophilic beta blocker on a once daily basis at relatively low dosage This should hopefully help foster good patient compliance in adhering to the therapy Moreover the benefits of cardioselectivity will still be maintained at low dosage (see below) which will not be the case if as in the case of a cardioselective lipophilic agent with a short clinical or plasma half life dosage is increased in order to achieve 24 hour effect

In conditions that possibly benefit from beta 2 blockade (migraine)[67] cardioselective beta blockers may have no useful action However blockade

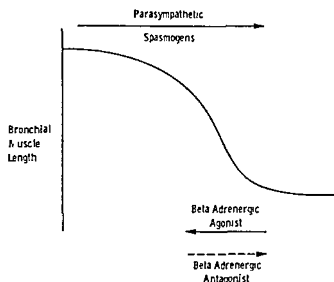

Fig 6 Dose response curve of bronchial muscle

of beta 2 receptors generally has *potentially* detrimental effects It is in these situations that a cardioselective beta blocker might be considered preferable to a non cardioselective beta blocker

Beta 2 blockade

I *Bronchus* Ideally claims for cardioselectivity should be based on data showing that the beta blocker inhibits the beta 1 effects of an agonist upon the heart while having little or no effect upon peripheral beta 2 effects—e g bronchodilation or vasodilatation Such circumstances pertained in the dog model shown in Fig 5 where propranolol produced both beta 1 and beta 2 blockade by shifting the isoprenaline/heart rate and airways pressure dose response curves to the right while atenolol modified only the beta 1 effects Metoprolol behaves in a similar fashion to atenolol[6] Harms [9] using in vitro and in vivo models has presented a table of cardioselective indices (see Table IV) This table is in roughly the reverse order of Hemsworth s table of lung/blood concentration ratios (Table III)

Tattersfield and associates[7] have devised a model in normal volunteers whereby beta 2 specificity or lack of it may be estimated The volunteers were given increasing doses of an inhaled beta 2 stimulant (salbutamol) and the effect upon airways conductance was measured in a whole body plethysmograph All subjects were later exposed to various beta blockers at two dose levels The doses of the various agents were chosen at levels thought to be approximately equipotent and clinically relevant Two hours after administration of the beta blocker the subjects were given salbutamol in increasing doses the effect again being measured in the whole body plethysmograph Dose ratios were estimated the dose ratio being that dose of salbutamol required to produce 50% maximum response (increase in airways conductance) for each drug and dividing this by the dose required to procude 50% response on placebo Table V shows dose ratios and it can be seen that atenolol and practolol caused the least interference with the salbutamol dose response curves and propranolol the most interference Cardioselectivity was illustrated in the case of atenolol by the fact that it caused the greatest fall in exercise heart rate (beta 1) but with practolol the least interference with airways conductance (beta 2) It can be seen that the higher the dose of a beta blocker the more of a beta 2 stimulant (salbutamol) is required to overcome the detrimental effects on airways conductance This confirms that the benefits of cardioselectivity tend to be lost at higher doses[7]

Clinical implications Work by Benson and colleagues[13, 14] (Fig 6) has shown that bronchi which are not dependent upon sympathetic drive to maintain their caliber will be little affected by potential spasmogens e g beta 2 blockade Thus, results of studies carried out on normal subjects whose bronchi are unstimulated must be regarded as potentially misleading Indeed it is likely that asthmatic subjects who are well with a normal or approaching normal FEV_1 (forced expiratory volume) are able to tolerate beta 2 blockade[15] However patients whose bronchi are dependent upon sympathetic tone to maintain their caliber—i e who fall on the steep part of Benson s dose response curve—are at definite risk from beta 2 blockade A study in a group of such patients[7] (Fig 7) demonstrated two important facts Under circumstances where seven different orally administered beta blockers at clinically relevant doses had produced approximately the same amount of beta 1 blockade (suppression of standing pulse rate and inhibition of the effect of isoprenaline upon the pulse rate) (1) a relatively highly cardioselective beta blocker was least likely to cause important branchoconstriction and (2) such a beta blocker (in contrast to non selective agents) almost completely preserved the

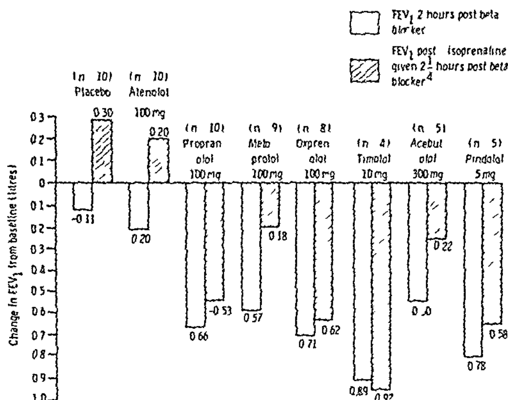

Fig 7 Effect of beta blocker and isoprenaline upon forced expiratory volume (FEV) in 10 responding (labile) asthmatic patients

2 bronchodilator action of isoprenaline should be emphasized that an asthmatic nt who is well and who falls on the flat on of Benson s dose response curve might be from beta 2 blockade at a different point in This fact is well illustrated (Benson person inication) by the asthmatic patient who n his FEV was 4 2 liters tolerated proprano mg well with no change in FEV However al months later (on no therapy) when he was ezy with an FEV of 2 9 liters he was unable olerate propranolol 80 mg propranolol sed his FEV, to fall to 1 7 liters and precipi d severe asthma It is thus recommended that on selective beta blocker should never be ed to a patient with reversible airways ction

- s cardioselective beta blockers like atenolol metoprolol do not confer absolute safety re will be occasional asthmatic patients who ond in an adverse way and it is recommended that atenolol and metoprolol should be prescribed alongside a beta 2 stimulant such as isoprenaline salbutamol or terbutaline in symptomatic asthmatic patients Another point worth emphasizing again is that cardioselectivity is a dose dependent property Thus the dose of a cardioselective agent should be kept as low as possible in patients at risk otherwise the advantages of cardioselectivity will be diminished [18]

Finally one ought to be aware of the possible role of metabolites in determining the cardioselective profile of a beta blocker Thus the acetyl metabolite of acebutolol which appears in the plasma at higher concentrations than its parent drug [9] is probably less cardioselective than acebutolol itself [9]

II *Peripheral blood vessels* Fig 5 showed that the non selective beta blocker not only competitively inhibited the beta 2 associated increase in bronchial airflow but also competitively inhibited the beta 2 associated increase in peripheral

function during treatment with a non selective compared to a cardioselective beta blocking drug this may be of importance in patients with renal disease

It would thus seem reasonable to prescribe a cardioselective agent to patients with renal dysfunction who require beta blocker therapy However a non selective beta blocker (nadolol)[111, 112] has been claimed to actually increase renal blood flow Such a claim is surprising and needs confirmation

6 MIGRAINE Non selective propranolol is almost certainly effective in treating migraine[8] Evidence to date (Behan personal communication) suggests that a cardioselective beta blocker is probably not effective in treating migraine However well controlled studies are required before this suspicion becomes fact

III *Metabolic*

a INSULIN SECRETION Resting insulin levels seem to be unaffected by beta blockers[115] However stimulated insulin secretion[116] is markedly suppressed by non selective beta blockers such as propranolol and only slightly suppressed by atenolol

b GLYCOGENOLYSIS AND GLUCONEOGENESIS It has been shown[1, 11] that the return of blood sugar to normal after insulin induced hypoglycemia was delayed by non selective but not by cardioselective beta blockade There are two possible explanations of this (1) that a beta 2 aspect of glycogenolysis is blocked by the non selective and not by the cardioselective beta blocker thus impairing the liver s ability to replenish the blood sugar and (2) non selective but not cardioselective beta blockers block lactic acid and glycerol (inhibits lipolysis) release from muscle[11] and thus the liver is denied substrate for gluconeogenesis

c. FREE FATTY ACIDS (FFAS) Basal FFA blood levels are suppressed equally by both selective and non selective beta blockers[5] although this effect appears to diminish in time However a stress induced increa e in FFAs tends to be better suppressed by a non selective beta blocker[11, 9] suggesting a de[illegible] beta 2 component

Clinical imp[illegible]

a. DIABETES [illegible] basal insulin secretion is unaffected by [illegible] blockers stimulated insulin secretion is [illegible]edly suppressed by non selective beta blo[illegible] This latter occurrence might explain the observations of Waal Manning[10] in which some patients while on propranolol had chemical diabetes but on metoprolol they had a normal glucose tolerance test These observations have not been confirmed in another study[116] in which in fact the post propranolol blood sugar tended to be somewhat lower than after a cardioselective drug (atenolol)

The importance of hypoglycemia associated with propranolol therapy has probably been much exaggerated[1] and most diabetic patients may be given this drug with safety[12] However hypoglycemia is undoubtedly a rare but important side effect with non selective beta blockade[121] particularly for diabetic patients on insulin[124, 125] fasting subjects (particularly children)[126, 127] post myocardial infarction patients[1] and possibly in patients undergoing hemodialysis[1] Moreover *the speed of* recovery of the blood sugar to normal is impeded by non selective beta blockers in contrast to cardioselective agents[11, 119] Interestingly hypoglycemic symptoms such as sweating and pallor appear to be unaffected by beta blockers the tachycardia is however suppressed more so by non selective than by cardioselective agents These observations have led these authors and others[130] to conclude that for the insulin-dependent diabetic patient requiring a beta blocker a cardioselective agent would be preferable

b FREE FATTY ACIDS It has been suggested by some that increased FFA levels in the post infarction period might be causing important dysrhythmias[131] However in a randomized study involving oral administration of either atenolol, propranolol or placebo[32] within hours of myocardial infarction (and continuing for one year) 24 hour ECG taping showed that the number of important ventricular dysrhythmias was the same for both agents (and indeed differed but little from placebo) It would thus appear likely that a non selective beta blocker will not confer an advantage in this area in terms of post infarction dysrhythmia prevention or indeed in dysrhythmias not associated with myocardial infarction[133]

Suggestions that high plasma FFA levels will increase atheroma formation and that a non selective beta blocker (in contrast to a selective agent) will hinder this process are entirely speculative

odilation might theoretically be expected to luce a lower blood pressure than a beta ker that does not

Resting blood pressure (supine and stand

ı

Iost studies[2,100] in which orally administered nolol has been compared with non selective a blockers on a crossover basis have indicated t atenolol is a superior antihypertensive agent ix of these studies atenolol was given in e daily doses and the non selective agent was *n either once[97] twice or four times daily*

In the remaining three studies both nolol and the non selective agents were given a twice daily basis Metoprolol also claims a ilar advantage However other studies em ying a crossover design and twice daily dosing e indicated that little difference exists between the antihypertensive effect of selective and ı selective agents On balance it is likely that a dioselective beta blocker is slightly more ef tive in lowering diastolic blood pressure

Exercise blood pressure

Dynamic It has been indicated that cardiose tive beta blockers administered on a crossover is either intravenously[1] or orally are erior to non selective agents in lowering the od pressure associated with dynamic exer [97,10,104] However more well conducted stud are required before these claims of atenolol l metoprolol can be regarded as proven

sometric Claims have also been made that lly administered cardioselective beta blockers more effective in preventing the rise in blood ssure associated with handgrip exercise wever others have not confirmed this and question must remain unanswered at pres

Stress hypertension

Iental Claims have been made[1] that orally ministered cardioselective agents are more ective than non selective agents in preventing rise in blood pressure associated with mental ess But confirmation of these results has not n forthcoming[107] and the question must nain open One study[8] has shown that non ective blockade (intravenous propranolol) used a diastolic pressor effect during mental ess

Insulin *treated diabetic During insulin hypo* cemia cardiovascular changes occur which are nilar to those occurring after adrenaline infu sion[109] Intravenous administration of a non selective beta blocker under these conditions blocks not only beta 1 receptors but also beta 2 vasodilator receptors with the result that a dia stolic pressor response of some 10 to 15 mm Hg occurs In contrast the pressor response is absent or diminished with a cardioselective beta blocker (metoprolol) administered either intrave nously[11] or orally[111] Thus for insulin treated diabetic patients requiring a beta blocker — the choice of a cardioselective agent is possibly pref *erable*

Smoking The act of smoking as with insulin induced hypoglycemia is associated with in creased adrenaline secretion tachycardia and an increase in both systolic and diastolic blood pressure (Fig 8) Intravenous administration of a non selective beta blocker during smoking did not diminish the systolic rise in blood pressure and caused a marked diastolic pressor response (15 to 20 mm Hg) In contrast cardioselective atenolol lowered the systolic blood pressure and did not cause a diastolic pressor response If these obser vations are confirmed in chronic oral studies there could be important implications in the choice of agent for the patient who insists on smoking and who also requires beta blocker ther apy

4 ANGINA Parratt and Marshall s work in animals has suggested that beta blockers with ISA and/or cardioselectivity in contrast to non selective beta blockers, are less likely to embarrass coronary hemodynamics Such a property might theoretically be beneficial to the anginal patient Astrom and Vallin have in fact claimed such an advantage for atenolol (5 mg intravenously) over propranolol (5 mg intravenously) but explain this on the basis that atenolol was asso ciated with a lesser rise in exercise blood pressure and thus lessened the afterload on the heart However other studies that have compared oral atenolol with propranolol and oxprenolol on a randomized crossover basis have shown no difference in antianginal effect

5 RENAL FUNCTION The minimal effect of cardioselective relative to non selective beta blockers upon effective renal plasma flow and creatinine clearance has led one group to conclude that treatment with atenolol would *appear not to cause significant reduction* of renal function and another investigator[4] to declare that he found a greater deterioration in renal

selective in contrast to a non selective beta blocker (with no ISA) Some patients with intermittent claudication thus will have a greater exercise tolerance with a cardioselective beta blocker

4 Antihypertensive control Because cardioselective beta blockers preserve beta 2 vasodilator action they are possibly slightly more effective antihypertensive agents than are non selective bete blockers

5 Stress hypertension Hypertension associated with increased adrenaline secretion—e g insulin induced hypoglycemia smoking and possibly mental stress is exacerbated (diastolic pressor effect) by a non selective beta blocker This is not the case with a cardioselective beta blocker

6 Renal function Renal function (effective renal plasma flow and creatinine clearance) is less compromised on cardioselective compared to non selective beta blockers (? nadolol excepted) This fact might be of importance to patients with already impaired renal function

7 Migraine Non selective propranolol is an effective prophylactic drug for migraine It is doubtful if cardioselective beta blockers will be effective

8 Blood sugar The majority of diabetic patients tolerate propranolol well The return of blood sugar to normal after insulin induced hypoglycemia is dependent to some extent on beta 2 receptor integrity (glycogenolysis and gluconeogenesis) A non selective beta blocker in contrast to a cardioselective beta blocker prolongs the hypoglycemic period Thus for patients at risk from hypoglycemia who require beta blocker therapy a cardioselective agent is probably preferable

Uterus Animal studies suggest that beta 2 ... increases the frequency and strength of ... of the gravid uterus[134]

... AL IMPLICATIONS Most studies[135 13] ...ate that beta blockers (propranolol and ...prenolol) may be given to the pregnant female ... harm to mother of child Indeed one ...dy[137] indicated a superiority of the beta block (oxprenolol) over methyldopa the former ...g associated with heavier placentas and birth ... Some[139 141] suggest that beta blockers ...ght harm the foetus However the fears that a ...n selective beta blocker might precipitate pre...ature contractions and miscarriage have not borne out

Cardioselective beta blockers tend as a group be hydrophilic However hydrophilicity is not essential factor for the expression of cardiose... ...kewise non selective beta blockers are ...lly lipophilic but lipophilicity is not an ... factor for expression of non selectivity ...ugh beta blockers as a group are effective and ...use few troublesome side effects an agent ... is cardioselective hydrophilic and non ...olized has in contrast to one which is ...n selective lipid soluble and metabolized sev... advantages in certain clinical areas

...inetic (hydrophilicity versus lipo...hilicity)

1 Blood levels and length of action Consistent ...tween patient peak blood levels (only ... to fourfold variation compared to twenty ...d with liver metabolized agents like proprano... and metoprolol) render a hydrophilic beta ... such as atenolol a very predictable drug the clinical situation and are probably contrib...ing to its narrow dose range Being unmetabo...l and renal excreted hydrophilic beta block... have a long biological action which enables a dose to be given on a once daily basis ... in 24 hour cover for both hypertension angina

2 The brain In man very little atenolol (hy...) enters the brain (about one twentieth the concentration of a lipophilic beta blocker) has a brain/blood ratio of approximately 0 1 1 ...d to 17 1 and 14 1 with propranolol and ...prolol (both lipophilic) respectively This ...ssibly accounts for (1) the low incidence of side effects relating to the CNS and (2) the disappearance of CNS side effects on changing from lipophilic beta blockers to atenolol

3 The kidney Hydrophilic beta blockers such as atenolol and nadolol are excreted virtually unmetabolized by the kidney However in the case of atenolol at glomerular filtration rates above 35 ml /minute (or serum creatinine of < 2 5 mg % or 300 mmol /L) there is no significant drug accumulation and the normal dose may be given Significant accumulation occurs in moderate to severe renal failure so that in order to achieve optimal therapeutic blood levels at glomerular filtration rates between 10 and 35 ml / minute (serum creatinine 2 5 to 5 0 mg % or 300 to 600 mmol /L) the daily dose should be halved and at glomerular filtration rates less than 10 ml /minute (serum creatinine > 5 0 mg % or 600 mmol /L) half the daily dose should be given on alternate days With lipophilic liver metabolized beta blockers like propranolol and metoprolol there is likewise a tendency for increased blood levels in severe renal failure (due to the accompanying liver dysfunction) These higher blood levels plus a marked accumulation of metabolites are an indication for dosage reduction

4 The elderly The elderly handle and tolerate hydrophilic beta blockers in a similar fashion to younger subjects Due to the liver dysfunction associated with aging (hepatic blood flow decreased 40 to 50% in the 70 years old subjects) lipophilic beta blockers like propranolol achieve blood levels in the elderly up to fourfold higher than in younger subjects this may account for the possible higher incidence of side effects in the elderly

Pharmacodynamic (cardioselectivity versus non selectivity)

1 Asthma At low doses atenolol and metoprolol are highly cardioselective (cardioselectivity is dose related) and are the beta blockers probably least likely to cause a fall in forced expiratory volume (FEV_1) in patients with reversible airways obstruction Also unlike non selective beta blockers they preserve the bronchodilator action of a beta 2 stimulant such as isoprenaline

2 Cold extremities Cold extremities can occur with all beta blockers but the temperature change is minimal on a cardioselective agent

3 Peripheral blood flow Peripheral blood flow during exercise is less compromised with a cardio

Table I Distribution of patients and control groups

	No of subjects M/F	Age (years) range mean ± S D	No of subjects with idiopathic GIT bleeding (%) mean age ± S D	No of subjects with aortic stenosis (%) mean age ± S D
Subjects with AS (Case group A)	152 103/49	7 74 44 4 ± 16 3	4(2 6%) 57.5 ± 6 9	–
Subjects with MS (Control group A)	152 55/97	12 77 46 7 ± 15 1	0	–
Subjects with GIT bleeding (Case group B)	154 96/58	11 87 57 4 ± 15.2	–	9(5.8%) 60 9 ± 7.3
Routinely admitted patients without GIT bleeding (Control group B)	154 73/81	17 79 58 4 ± 14 3	–	3 (1.9%) 57 3 ± 27.5

M = male F = female GIT = gastrointestinal tract AS = aortic stenosis MS = mitral stenosis.

Table II Sources of bleeding and incidence of AS in patients with GIT bleeding (Case group B)

Source of bleeding	No of patients	Subjects with aortic stenosis
Duodenal ulcer	94	1
Diaphragmatic hernia	15	1
Diverticulosis of colon	5	0
GIT tumors	7	0
Esophageal varices	2	0
Drug induced	7	0
Idiopathic	24	7

Table III The age distribution according to sex in Case group A (aortic stenosis) and Case Group B (GI bleeding)

Age (year)	Case Group A F/M	Case Group B F/M
- 20	8/13	0/2
21 30	5/6	2/8
31-40	3/14	4/7
41 50	14/22	6/17
51 60	10/29	18/17
61 0	8/19	16/24

findings of A[illegible] typical findings at cardiac catheterization [illegible] AS proven at autopsy In the anemic patient [illegible] tolic murmur was regarded as significant [illegible] when it remained following blood transfusion [illegible] subsequent restoration of the hemoglobi[illegible] to normal values

Statistical analysis was done using the chi square test

Results

The distribution of the patients in the four groups is given in Table I and the sources of GIT bleeding in Case group B is given in Table II In Table III the age and sex distribution of the patients in Case groups A and B are summarized Seven patients (five males and two females) in Case group A (4 6%) had duodenal ulcer (three of them with melena) and four males (2 6%) had idiopathic GIT bleeding (in three of them repeated laparotomies did not disclose the source of bleeding) Their mean ages were significantly higher than that of the total group A ($p < 0.05$) (Table I) Only four patients (two males two females) of the control group A (2 6%) had duodenal ulcer and none had idiopathic GIT bleeding (Table I) No statistically significant difference was found between the patients with idiopathic GIT bleeding those with duodenal ulcer and the non bleeders regarding the cardiac output valve area use of anticoagulants or antiplatelet aggregating agents and incidence of diabetes mellitus and arterial hypertension Syphilis was not detected among the presently examined patients

Nine patients of Case group B (5 8%) had AS (in five of them the diagnosis was confirmed by autopsy in two by catheterization and in the other two it was based on clinical criteria [a to d]) Their mean age was significantly higher than that of the total Case group B ($p < 0.005$) (Table

pite the sophisticated procedures used in the nosis of bleeding from the gastrointestinal (GIT) it is sometimes impossible to estab the source of the bleeding[1] An association een GIT bleeding of undetermined source aortic stenosis (AS) has been reported and hereby tried to assay the incidence of GIT ding of established and of undetermined on among patients with documented AS as well he incidence of AS in patients with GIT ding of undetermined origin

and methods

he patient material (data as to age and sex are n in Table I) consisted of

Case group A—152 patients with proven AS underwent cardiac surgery between the years 1978

Control group A—152 patients with proven ral stenosis (MS) who underwent cardiac sur y between the years 1971 1975

ll patients underwent preoperative cardiac in which cardiac output and aortic mitral valve areas were determined All the ients were examined diagnosed and operated in the same department In all of them the s was severe enough to warrant opera —ie in AS a gradient of at least 60 mm Hg een the aortic and the ventricular systolic pressures and in MS all patients were in function al Class of late II or III or suffered from arterial embolizations In 77 out of the 152 patients with AS an associated aortic insufficiency was found while in only 51 out of the 152 patients with MS was mitral insufficiency also found

GIT bleeding was defined as a drop of the hemoglobin to less than 11 5 g /dl in males and less than 10 5 g /dl in females associated with either three consequent positive guaiac stool examinations for the presence of occult blood or when melena occurred

All patients with GIT bleeding underwent a complete GIT x ray series including routine rec toscopies In 85% of the patients these examina tions were performed at least twice The bleeding was considered idiopathic when its source was not detected by the above mentioned examination Eight patients had gastroscopies (and in two of them-colonoscopies) celiac angiography as well as explorative laparotomy however even these procedures failed to establish the source of bleed ing In order to examine the incidence of AS among patients with idiopathic GIT bleeding two additional groups of patients were selected

1 Case group B—154 patients hospitalized for GIT bleeding between the years 1971 and 1975

2 Control group B—154 age matched patients selected from 154 consecutive admissions during 1974 who had no GIT bleeding (Table I)

The diagnosis of AS was established when at least four of the following criteria were present namely (1) systolic aortic ejection murmur radi ating to both carotid arteries (2) a low and slow radial pulse (3) a calcification of the aortic valve on chest x rays (4) typical echocardiographic

the AS does not justify this major operation Cattell (quoted in Ref 7) proposed a completely different approach namely a blind resection of the ascending colon This mode of treatment seems to be justified by the reports of GIT bleeding in patients with AS found to originate from the right colon[8, 9]

Summary

A retrospective study was done in order to examine the association between aortic stenosis (AS) and gastrointestinal tract (GIT) bleeding Four groups of patients included a group of 152 patients with AS a control group of 152 patients with MS, and another two groups of 154 patients each with and without GIT bleeding

GIT bleeding of known and of idiopathic sources was significantly more prevalent among patients with AS (three and four patients respectively) than among those with MS (none) Moreover AS was significantly more prevalent in association with idiopathic GIT bleeding (seven out of 24 29 1%) in comparison to its association with bleeding from a known source (two out of 130 1 5%) and its incidence in routinely admitted patients without GIT bleeding (three out of 154 1 9%)

This study supports the assumption that GIT bleeding may be associated with AS

en of them had AS—i e 29 1% of the its with idiopathic GIT bleeding (seven out 4) in contrast to only 1 5% (two out of 130) AS confirmed by autopsy among the with an established source of GIT bleed p < 0 001) (Table II) Only three cases of AS y diagnosed (1 9%) were found in the trol group B (p < 0 05)

he age sex and type of valvular defect in four ips of patients with GIT bleeding and valvu efect are summarized in Table IV

on

presently reported data reaffirm the asso between AS and idiopathic GIT bleeding latter being significantly more prevalent ong patients with AS compared to the control with MS In addition the incidence of AS our patients with GIT bleeding (Case p B) was significantly higher than among ely admitted patients without GIT bleed Control group B) (nine versus three Table I) over almost one third of the idiopathic GIT rs had associated AS (Table II) an inci ice comparable with the one reported by Wil and Boston [5]

n the present report the mean age of the ients having AS associated with GIT bleeding significantly higher than that observed in ir respective groups (Table I) Assuming that atherosclerotic process progresses with ancing years it might be possible that involve of both the aortic valve and the GIT vessels atherosclerotic lesions in older patients could responsible for this peculiar association other possible explanation for the GIT bleeding might be an ischemic damage to the intestinal vessel walls due to a decreased cardiac output in patients with AS [4] This possibility could not be supported by our data i e there was a lack of significant differences in cardiac output between GIT bleeders with AS or with MS The high incidence of syphilis found by Williams and Boston[5] among their patients with AS and idiopathic GIT bleeding was not noted among the presently examined patients Duodenal ulcer was found in 4 6% of our patients with AS (seven out of 152) a rate significantly higher than in the control group with MS (2 6%) McNamara and Austen[7] diagnosed duodenal ulcer in 18 of their 26 patients with AS We are unable to forward a reasonable explanation for this interesting association Many patients with AS are treated postoperatively with anticoagulants or antiplatelet aggregation agents Since duodenal ulcers have a propensity to bleed especially when the patient is on anticoagulants a search for duodenal ulcer might be recommended in every patient with AS facing operation

In a considerable percentage of patients with AS and GIT bleeding the GIT x rays series endoscopy angiography and explorative laparotomy failed to reveal the source of the bleeding [5, 7, 9, 10] Some of these quite aggressive diagnostic procedures bear considerable morbidity and mortality and may be dangerous especially in patients with valvular diseases McNamara and Austen[7] reported that recurrent episodes of GIT bleeding ceased following aortic valve replacement However these patients are frequently afflicted also by other valvular defects are of an advanced age and in many of them the severity of

patients with abnormal (low or high) plasma renin activity values[17] were excluded from the study A part of the study (Protocol I) was carried out in the University Hospital Utrecht The Netherlands and the other part (Protocols II and III) in the János Hospital Budapest Hungary The investigations were carried out according to the Declaration of Helsinki The nature of the investigation was fully explained to each person and written consent was obtained from them All antihypertensive treatments were discontinued 1 month before the study All participants (except three hypertensive patients) were placed on a diet containing 200 mEq Na per day for 4 to 7 days before the study In three members of the hyper tensive group H (see below) the daily Na intake was 150 mEq

Protocols

Protocol I Moderate NaCl loading in four healthy subjects (group N_1) and in nine hyperten sive patients (group H) Two days before the study 40 μg DDAVP (Minirin Ferring AB Mal mo Sweden) was given intranasally (20 μg into each nostril) three times a day On the day of the study of 7 A M and 11 A M 40-40 μg DDAVP were given intranasally The study began after an overnight fast and water deprivation at 9 A M After two 30 minute control clearance periods (baseline study) 1 liter 2 92% NaCl solution (500 mEq Na) was infused during 60 minutes During this period and in the next hour altogeth er six 20 minute clearance periods were run The study was concluded by two 30 minute periods Altogether 10 periods were done during 4 hours

Protocol II/a High NaCl loading by rapid *infusion in four healthy subjects* (group N_2) The procedure was the same as in Protocol I except 2 liters 2 92% NaCl (1 000 mEq Na) were infused during 60 minutes an intravenous dose of 4 μg DDAVP was given at 9 A M in addition to the two intranasal doses given at 7 A M and 11 A M

Protocol II/b High NaCl loading by rapid infusion in three hypertensive patients (group H_2) The procedure was the same as in Protocol I except 1½ liters 2 92% NaCl were infused during 80 minutes

Protocol III High NaCl loading by slow infusion in seven healthy subjects (group N_3) Prepatatory DDAVP treatment was not given but during the whole experiment 500 mU lysine-vasopression per hour were infused intravenously No baseline periods were run One liter 2 5% NaCl was infused *intravenously* during the first two hours and 500 ml 5% NaCl was infused during the second two hours Altogether 854 mEq Na were given During the last hour one 60 minute clear ance period was performed

Urine was collected by an indwelling catheter Blood samples were taken through an indwelling venous catheter (Butterfly Abbott) in periods 1,2 5 7 and 9 of Protocols I II/a and II/b and at midpoint of the clearance period *of Protocol* III

rine and blood samples were analyzed for creat ine sodium potassium (in all groups) calcium agnesium phosphate (in all but group N_1) and r uric acid (only in groups N and N_2) by ocedures applied to the Technicon Autoanalyz Chloride was measured by a chloridometer All n clearances were expressed as a percentage of FR (creatinine clearance) When calculating Ca nd Mg clearances it was assumed[16] that 60% of e total plasma Ca concentration and 70% of the tal Mg concentration underwent ultrafiltration the glomerulus Osmolality was determined by n Advanced Osmometer Cosm and T_{H_2O} were lculated according to standard formulas In rder to save space in the Tables contracted data f periods 1 and 2 (baseline) 3 to 6 (during aCl loading) and 7 to 10 (after loading) are cluded For unity period 6 was included in the during NaCl loading contracted data of Proto ols I and II/a Correlation coefficients and gression lines were computed by the method of ast squares Statistical significance was deter mined by the paired t test except when different groups were compared then the unpaired t test was used Data are presented as mean ± SEM

Results

Baseline relationship between Cosm and $T^c_{H_2O}$ A normal relationship between Cosm and $T^c_{H_2O}$ was established during high NaCl intake by including all baseline values of the healthy sub jects (groups N_1 and N) and hypertensive patients (groups H_1 and H_2) The relationship is expressed by the formula $y = 0.58 \times + 0.27$ ($r = 0.99$ $p < 0.001$) in the healthy subjects and by $y = 0.63 \times - 0.03$ ($r = 0.99$ $p < 0.001$) in the hypertensive patients No statis tical difference was found between the slopes (Fig 1)

Effect of a moderate intravenous NaCl load on the baseline relationship between Cosm and T_{H_2O}

Healthy subjects (group N_1) The time course of changes in Cosm and T_{H_2O} can be seen in Fig 2

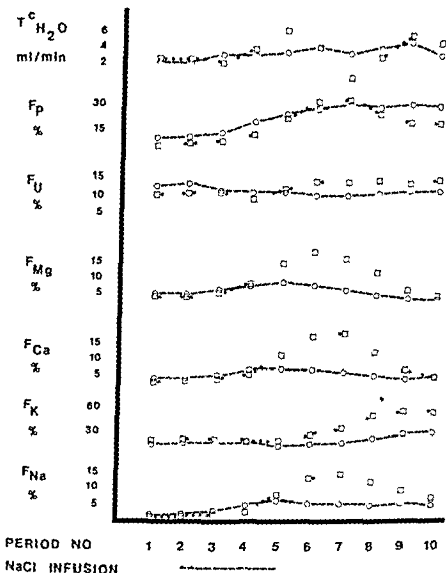

Fig 4 Time course of changes in *fractional* excretion of Na K Ca Mg uric acid *(U)* and phosphate *(P)* as well as in T^c during and after moderate NaCl loading *(circles)* and high NaCl loading *(squares)* $p < 0.05$ $p < 0.01$ $p < 0.005$ $p < 0.001$

NaCl reabsorption in Henle s loop Our most striking finding was the disruption of the normal correlation between Cosm and T_{H_2O} with some times positive free water clearance values when healthy subjects were infused with high intrave nous NaCl loads Our results are in agreement with those obtained in other studies of the hydrated dog and of human subjects [6] suggesting that volume expansion inhibits fractional NaCl reabsorption in the distal nephron in a dose related fashion Depression of the fractional NaCl reabsorption in the distal nephron obviously played a definitive role in the exaggeration of natriuresis when high NaCl loads were given to healthy subjects The peak fractional Na Ca and Mg excretions were simultaneous with the decrease in T_{H_2O} (Fig 4) also supporting the hypothesis that the reabsorption of interrelated ions [4] was inhibited in the distal nephron If fractional phosphate excretion is (within limitations) an acceptable proximal marker [9] then the lack of difference in phosphaturia between the moderate and high NaCl groups seems to support the distal interpretation (Table II)

An alternative explanation for the observed depression of $T^c_{H_2O}$ would be insufficient osmotic equilibration in the collecting tubules as a result of excessive osmotic diuresis or/and submaximal ADH effect This however probably was not the case because osmotic diuresis (Cosm) was not

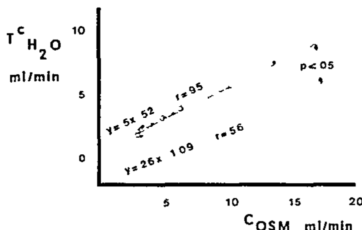

Fig 3 Relationship between Cosm and $T^c_{H_2O}$ in healthy subjects under the influence of "moderate" NaCl loading *(group N circles)* and high NaCl loading *(group N black stars)*

significantly higher level in this group than in oup N_1 but there was no significant difference Na Ca Mg and P excretion between the oups (Table I)

Effect of high intravenous NaCl loads on the ationship between Cosm and T_{H_2O} established ring moderate NaCl loading

Healthy subjects (group N_2, Protocol II/a) The ationship during high NaCl loading is pressed by the formula $y = 0\,26 \times + 1\,09$ $= 0\,56$ $p < 0\,001$) The slope of this line was nificantly different from that of moderate ading ($p < 0\,05$) The correlation between sm and $T^c_{H_2O}$ became much less close after a gh NaCl load than after a moderate load (Figs and 3) There was a significant difference $< 0\,001$) between the mean maximum and nimum $T^c_{H_2O}$ values (6 74 ± 0 48 ml /minute vs 2 ± 0 61 mL/minute) obtained during high aCl loading but without a significant difference tween the corresponding mean Cosm values 17 ± 1 24 ml /minute vs 11 92 ± 1 57 ml / nute) suggesting that the rise of Cosm per se as not responsible for the dramatic decrease in o (Fig 2) The rises in fractional Na K Ca Mg d Cl excretions were significantly higher after gh NaCl loading than after moderate NaCl ading (Table II Fig 4) but there was no nificant difference in P excretions It is inter ting that fractional uric acid excretion slightly creased after moderate NaCl loading but sig ficantly increased in response to a high NaCl ad

It should be noted that during administration a relatively high dose of NaCl by *slow* intravenous infusion *(group N_3 Protocol III)* the correlation between changes of Cosm and T_{H_2O} remained excellent $r = 0\,99$, $p < 0\,001$)

Hypertensive patients (group H_2, Protocol II/ b) The relationship between Cosm and T_{H_2O} (ex pressed by the formula $y = 0.27 \times +0\,59$) was less close after high loading ($r = 0\,49$ $p < 0\,05$) than after a moderate load in group H_1 ($r = 0.82$ $p < 0\,001$) There was a significant difference ($p < 0\,001$) between the mean maximum and minimum $T^c_{H_2O}$ values (5 87 ± 0 43 ml /minute vs 0 86 ± 0 59 ml /minute) but no significant difference was found in the corresponding mean Cosm values (11 09 ± 1 42 ml /minute vs 7 92 ± 1 81 ml /minute)

Discussion

This study clearly shows that acute NaCl loading may depress T_{H_2O} not only in hypertensive patients[9, 10] but also in healthy subjects (Figs 1 to 3) In earlier studies carried out in dehydrated healthy subjects this has not been reported because during intravenous administration of hypertonic NaCl solutions there was no evidence for an upper limit of T_{H_2O} as the increasing delivery from the proximal nephron enhanced NaCl transport out of the ascending limb of Henle s loop[8] However in the previous studies only moderate NaCl doses were used[13] and the present results show that depression of $T^c_{H_2O}$ occurred apparently as a dose related consequence of acute NaCl loading The augmentation of $T^c_{H_2O}$ at any rate of distal delivery of NaCl was significantly less during high NaCl loading than after moderate NaCl loading suggesting impaired

Echocardiographic pattern of motion of the aortic root as a correlate of left atrial volume changes*

G Biamino
H J Wessel
W Schlag
R Schroeder
Berlin W Germany

The pattern of motion of the aortic root is characterized by parallel movement of its anterior and posterior walls and is usually simple to record echocardiographically The distance between the two walls as a correlate of the diameter of this vascular structure -4 and evaluations of the aortic leaflet motion between the two dominant echos- have been the subject of several investigations Recently attempts have been made to correlate the typical systolic motion of the aortic root in the direction of the anterior wall of the thorax with the stroke volume of the left ventricle

When recording the echoes of normal aortic leaflets and particularly during postoperative studies of Bjork Shiley aortic valve prostheses it was noted that the systolic motion of the aortic root towards the anterior thorax wall uniformly continues beyond closure of the valve This finding indicates that a direct correlation between stroke volume of the left ventricle and systolic aortic root motion is doubtful

In this study we have therefore attempted to correlate the motion of the aortic root with further echocardiographically detectable structures and with the ECG the PCG the carotid pulse curve or the apexcardiogram as well The results indicate that the echocardiographically detectable motion of the aortic root is not caused by the volume ejected into the aorta during systole but is an index of changes in volume of the left atrium *

Similar conclusions have been reported by Strunk and associates in recent studies comparing hemodynamic and cineangiographic findings with the simultaneously recorded echocardiographic pattern of the posterior aortic wall

Material and method

Forty-eight male and 34 female patients aged between 10 and 68 years (average age 54 years) were studied In 32 cases the studies were performed during routine examinations after implantation of aortic and/or mitral valve prostheses (Bjork Shiley tilting disc valve) There were no clinical or echocardiographic signs of malfunction of the prostheses The prostheses in the aortic position were implanted with a standardized operative procedure in such a way that the asymmetric strut was positioned left anteriorly between the two coronary ostia In consequence the disc opening movement turned in a left anterior direction toward the ultrasonic beam In the mitral position the strut of the prostheses was placed so that the protodiastolic major disc pivoted toward the aortic outflow tract in the direction of the septum and, thus also in a ventral direction toward the transducer * In the remaining 50 cases there was no sign of an aortic or mitral defect

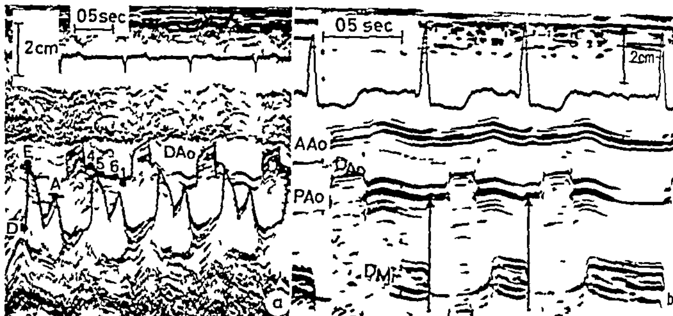

Fig 3 *a* On simultaneous registration of the posterior walls of the aortic root and of the tilting disc of the valve prosthesis (D_A) and of the anterior mitral leaflet *(D E A)* it can be clearly seen (1) that Point 4 in aortic root motion is concomitant with the opening slope D E and (2) that the posterior movement of the aortic root from Point 6 to Point 1 corresponds to the A wave *b* This echogram records the tilting discs of the aortic (D_A) and mitral valve (D_M) prosthesis Due to atrial fibrillation the dorsally directed motion from 6 to 1 is absent Note the small notch in the aortic root motion at the beginning of the isometric ventricular contraction (↑)

The echocardiographic examinations were carried out with a scope display echocardiograph unit manufactured by Organon Teknika with a Polaroid camera and Honeywell strip chart recorder with chart speeds of 25 50, and 100 mm/sec The ultrasound frequency was 2 25 MHz The transducer was placed in the second to fifth intercostal space (usually the third or fourth) 2 to 5 cm left parasternal A complete sector scan was made by the usual method and individual structures in differing intercostal spaces were separately recorded with the patients lying on their backs and the trunk elevated to approximately 30 degrees

ECGs and in most cases PCGs were simultaneously recorded routinely at the second left intercostal space parasternally Apexcardiograms or carotid pulse curves were also obtained

The results reported in this study were found to be reproducible by different examiners and independent of age and sex of the patients

Results

During sinus rhythm six points in the parallel echo curves of the anterior and posterior walls of the aortic root can be regularly identified in patients with aortic valve prostheses (see Fig 1b) In contrast in patients with normal aortic valves, it is frequently impossible to determine Points 2 and 3—opening and closing of the aortic valve—with accuracy [5] This accounts for the impression that there is a correlation between the time course of the ventral movement of the aortic root and the mechanical systole of the left ventricle [1,8] The two representative examples in Fig 1 show that the motion of the aortic root in the direction of the anterior thorax wall definitely continues beyond closure of the valve It is also clear that the posteriorly directed aortic root motion does not begin (Point 4) until after the second heart sound The steepest part of the aortic root curve is that between Points 4 and 5 thereafter a plateauing occurs At Point 6 (immediately after the P wave in the ECG) the aortic root accelerates again in the direction of the posterior chest wall until Point 1 is reached The course of the curve between Points 1 and 2 is practically horizontal whereby a small wave can occasionally be noted concomitantly with sets 1 and 2 of the first heart sound (mainly at the posterior wall of the aortic root)

The objective was thus to correlate the motion of the aortic root not only with the ECG and the PCG but also with the carotid pulse curve (CP) the apexcardiogram (ACG) and the echocardio-

Fig 5 The influence of contraction of the left atrium (complete AV block) on the echographic pattern of the aortic root *(a)* and the anterior mitral leaflet *(b)* See text for details

2 Point 5 indicates the end of the rapid filling phase

3 The posteriorly directed acceleration from Point 6 to Point 1 can only be clearly identified in patients with sinus rhythm (compare Figs 3a and 3b)

Fig 3b also shows that the small wave between Points 1 and 2 of the aortic root movement occurs during the isovolumetric phase of the left ventricle as the mitral valve has already closed at this point and the aortic valve has not yet been opened by the pressure rise in the left ventricle Final proof that the dorsal accelaration of the aortic root curve from Point 6 to Point 1 is only an expression of a change in volume in the left atrium after its contraction is supplied by Fig 4 A sinus rhythm prevails in the case of this patient with a Bjork Shiley prosthesis Each P wave (vertical lines) is followed by the previously mentioned dorsally directed motion of the aortic root. When a supraventricular extrasystole without atrial excitation occurs there is no dorsal displacement from Point 6 to Point 1 Also remarkable is the fact that a slow motion of the aortic root toward the anterior chest wall can be observed during the compensatory pause after the supraventricular extrasystole This finding is completely contrary to a hypothetical correlation between the ejection volume of the left ventricle and the ventral motion of the aortic root

The results previously obtained have included the finding that both walls of the aortic root are subject to presystolic dorsally directed motion apparently as a consequence of the contraction and the associated active emptying of the left atrium This would indicate that motion of the posterior wall of the aortic root is consistent with its anatomical juxtaposition and is due to the dorsally directed contraction of the anterior atrial wall counterpart of the simultaneous ventrally directed motion of the posterior wall of the left atrium (see Fig 1a) Consequently the parallel movement of the anterior wall of the aortic root should be regarded as purely passive If this hypothesis is correct changes in the volume of the left atrium will then influence the pattern of motion of the aortic root independently of the course of ventricular contraction

In order to investigate this possibility patients with complete AV blocks were echocardiographically examined Sections from a continuous echocardiogram or the aortic root (Fig 5a) and the mitral valve (Fig 5b) from each patient were superimposed in order to demonstrate the influence of atrial contraction on these two structures and to correlate timing As can be seen in Fig 5b an opening movement of the mitral valve (correlated with P waves No 1 3 5 7 8) or a change in the configuration of the E wave (P wave No 2) corresponds with each excitation and subsequent atrial contraction during the ventricular diastole If atrial contraction occurs during the ventricular systole however recognition of this finding in the pattern of motion of the mitral valve (P waves No 4 and 6) is precluded

On the other hand each contraction of the

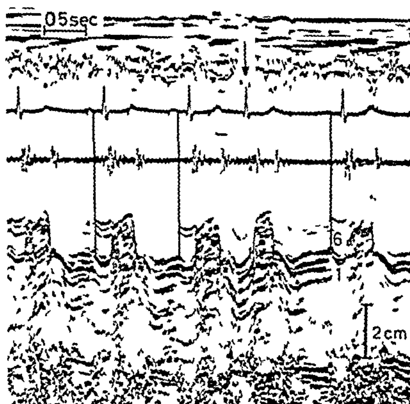

Fig 4 The typical posterior motion of the aortic root from Point 6 to Point 1 is noted at the end of each P wave this is absent in the case of a supraventricular extrasystole (↓) without atrial excitation

graphic movements of the mitral valve (Fig 2) A comparison of the time course of aortic root motion with the simultaneously recorded carotid pulse curve (Fig 2a) demonstrates that the characteristics of the two curves do not coincide at any time Two observations are of particular interest

1 Taking pulse wave speed into account it can be seen that at the time of the percussion wave (P) in the CP curve motion of the aortic root in the ventral direction has just begun

2 The ventral motion of the aortic root continues with the same slope even after the tidal wave (T) in the CP curve

Shortly after the second heart sound and the dicrotic notch (D) in the CP curve the aortic root begins to move toward the posterior chest wall (Point 4) This Point 4 would therefore appear to correspond with the opening motion (D E) of the mitral valve (Fig 2b) and to be directly before the 0 point of the ACG (Fig 2c) Fig 2c clearly shows that interruption of the steep movement of the aortic root toward the posterior chest wall (Point 5) coincides with the end of the rapid filling phase (rf) in the apexcardiogram The flat section of the aortic root curve from Point 5 to Point 6 reflects the slow filling phase (sf) of the ACG Point 6 then corresponds temporally with the end of the P wave in the ECG and with the beginning of the A wave of the anterior mitral leaflet (Fig 2d) The following aortic root motion toward the posterior chest wall is accompanied by contraction of the atrium The end of this coincides with the *a* wave in the ACG and with Point 1 of the aortic root curve In view of the coincidence of timing with the *c* point in the ACG the small wave at the posterior aortic root wall and before opening of the valve probably represents the isovolumetric course of contraction of the left ventricle in the echocardiogram

In a number of patients aortic and mitral valve motion was simultaneously recorded

In Fig 3a the aortic root motion was clearly identified in a patient with an aortic valve prosthesis and a normal mitral valve and in Fig 3b it was identified in a patient with both aortic and mitral valve prostheses

The tracings show

1 Point 4 coincides exactly with the opening movement of the mitral valve (DE)

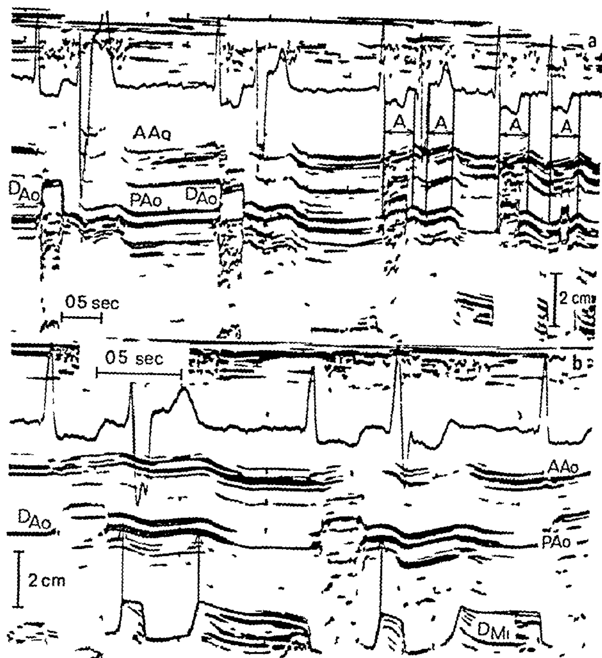

Fig 8 Echograms of the aortic root of a patient with a Bjork Shiley prosthesis in the aortic and mitral positions with atrial fibrillation and ventricular extrasystoles The early extrasystoles cause mitral valve closure but do not induce opening of the aortic valve *(b)* In spite of this the diastolic motion of the aortic valve is ventrally directed even after an extrasystole *(a* and *b)* The duration of this movement *(A)* is only slightly influenced by the left ventricular ejection period *(a)* *b* again shows that the diastolic posterior motion of the aortic root does not take place until after the mitral valve has opened (↓)

sequently the following clearly recognizable ventral displacement of the aortic root cannot be taken as an index of a displacement of volume from the ventricle to the aorta As can be seen at the right hand edge of Fig 8a the ventrally directed motion of the aortic root also appears to be little influenced in its amplitude and duration by the duration of aortic valve opening and by the ejection period of the left ventricle respectively

On the other hand this anterior aortic motion cannot represent the retrograde flow in the left atrium since the mitral valve is closed immediately on occurrence of the extrasystole as a result of the induced pressure rise in the left ventricle

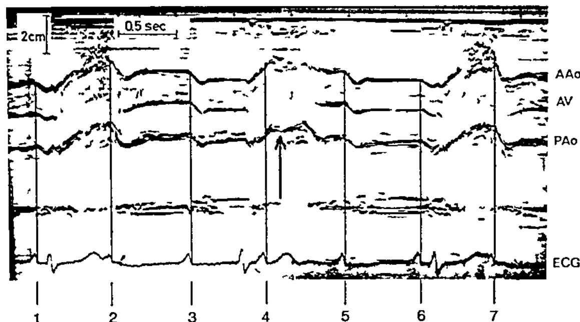

Fig 6 Echographic pattern of the aortic root (*AAo* = anterior wall *PAo* = posterior wall of the aortic root *AV* = aortic valve) of a patient with a complete AV block Note (↑) the interruption of ventral movement of the aortic root caused by atrial contraction Each following atrial contraction also influences the pattern of aortic motion.

atrium causes dorsally directed motion of the aortic root (P waves Nos 1 3 5 6 8) or acceleration of such motion (P waves Nos 2 7) regardless of the phase of ventricular excitation or contraction in which it occurs as is clearly shown by Fig 5a The echocardiographic pattern of the aortic root motion after the P wave No 4 in Fig 5a and Fig 6 also makes it apparent that atrial contraction can even interrupt the ventrally directed motion of the aortic root

The complete independence of the aortic root motion from the systolic ejection of the left ventricle into the aorta could be definitively demonstrated in a patient with a Bjork Shiley prosthesis and complete AV block (Fig 7) at the opening of the prosthetic disc the time of maximal flow in the aorta the aortic root does not move anteriorly but dorsally if atrial contraction occurs concomitantly (P waves No 1 and 3)

Finally Fig 5a (like Fig 1) also clearly shows that the anterior movement of the aortic root correlates with a flatter dorsally directed motion of the posterior wall of the left atrium This finding reflects the expected increase in volume of the left atrium during the ventricular systole

After having shown that a quantitative correlation between the effective systolic volume ejected by the left ventricle and the aortic root motion does not exist the influence of the ventricular systole on the echo pattern of the aortic root was examined

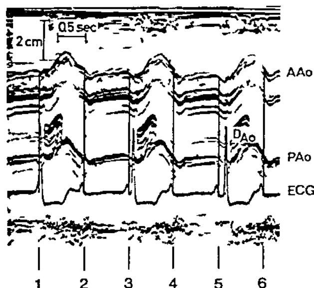

Fig 7 Echograms of the aortic root of a patient with a Bjork Shiley aortic valve prosthesis and complete AV block The aortic root motion is dorsally directed after the P waves 1 and 3 although the aortic valve has already been opened by ventricular contraction.

The echocardiograms of patients with ventricular extrasystoles (Fig 8a) demonstrate that the aortic valve (in this case prosthetic) does not open at all if the extrasystole occurs early Con

Decisive for our interpretation namely that there is no direct correlation between antegrade ejection and ventral aortic root motion are the findings which show the existence of such a motion after extrasystolic ventricular contraction *without* opening of the arotic valve (Fig 8) and on the other hand a dorsally directed movement of the aortic root when the aortic valve is already open in the case of coincidence of ventricular and atrial systoles (Figs 6 and 7)

In view of these findings the claim of Pratt and colleagues* that aortic root motion can be taken as an index of stroke volume is no longer tenable If changes in the amplitude of aortic root motion are to be taken as correlates of stroke volume (to be exact changes in the volume of left atrium) at all they can only be evaluated when it is certain that neither size nor compliance of the left atrium change This would in turn mean that the amplitude of aortic root motion can only be regarded as a sensitive parameter for assessing the ejection capacity of the left ventricle in acute experiments and with patients *without* mitral insufficiency or atrial septal defect

Summary

The movement of the aortic root under resting conditions was analyzed echographically in 82 patients (32 were postoperative examinations of Bjork Shiley arotic and/or mitral valve prostheses) Additionally ECG PCG carotid pulse curve or apexcardiogram were recorded simultaneously in the majority of the cases In view of the time correlation between these noninvasive parameters the results clearly show that both ventrally and dorsally directed motions of the aortic root during the cardiac cycle only reflect the change in volume of the left atrium Thus aortic root motion might if at all be an indir index of left ventricular stroke volume and or so if sinus rhythm is present and no mitr insufficiency or atrial septum defect exist

(Fig 8b) The ventral motion of the aortic root probably reflects only the antegrade pressure passive flow from the pulmonary system into the left atrium

Discussion

It has been reported that the two dominant echoes comprising the root of the aorta are probably the easiest of all cardiac echoes to record However this statement is contradicted by the lack of studies on the pattern of motion on this vascular structure which is automatically recorded echocardiographically in the course of assessing the functioning of aortic valves The cyclical motion of the aortic root was subdivided simply into a systolic movement towards the anterior thorax wall and a diastolic dorsally directed movement The cause of this motion was thought to be the course of contraction of the left ventricle either in the sense of a possible centrifugal effect or as the consequence of the effective antegrade ejected volume [1] Only the presystolic dorsally directed motion of both walls of the aortic root for example as shown in Figs 1 and 3 was attributed to the contraction of the left atrium since it is absent in the presence of atrial fibrillation [4]

The finding that the ventrally directed motion of the aortic root always continued beyond valve closure has been reported but not discussed in several papers [4-6] The lack of interpretation of this phenomenon may be due to the fact that the opening and closing motions of the aortic valve can only be recorded exactly in about 30% of normal cases and that multiple scarcely analyzable echoes between the aortic root limits are registered [5] in the case of diseased aortic valves particularly when stenosis is present

Confirming the conclusions of Strunk and associates [13] the results of our study clearly show that the diastolic pattern of the aortic root in the echogram corresponds exactly with the time course of the physiological changes in volume of the left atrium (Figs 2 3 4 and 5) The dorsally directed motion of the aortic root (Point 4) does not begin simultaneously with closure of the aortic valve (Point 3) but *always* begins with the DE slope of the anterior mitral leaflet This initially relatively steep motion flattens out (Point 5) at the end of the rapid filling phase of the left ventricle (rf) and then demonstrates repeated acceleration (Point 6) in concomitance with the A wave of the anterior mitral leaflet i e through atrial contraction finally reaching the lowest point Point 1 If atrial fibrillation occurs the acceleration wave from Point 6 to 1 is absent

The motion of the anterior aortic root wall which is parallel to the posterior must therefore be regarded as passive transmission of the motion of the anterior left atrial wall via the posterior aortic wall The reported larger amplitude of the maximal excursion of the anterior wall probably has no relation to an asymmetrical extension of the aortic wall during the ejection period but may be only the result of an oblique echo path and thus the expression of differing projections In this regard it is significant that no marked differences in the diameter of the aorta were detected throughout the entire cardiac cycle

If the entire diastolic motion of the aortic root is apparently correlated with the process of emptying of the left atrium into the left ventricle one must discuss to what extent the anterior systolic motion of the aortic root is also the expression of a change in volume of the left atrium in the sense of an increase in volume as physiologically expected during the left ventricular systole The primary finding in favor of this hypothesis is that the ventral motion of the aortic root is accompanied by a dorsally directed motion of the posterior wall of the left atrium which although not so pronounced can frequently still be clearly determined echographically (Figs 1a and 5a) Several of the findings presented in this study do not support the assertion that there may be a *direct* quantitative correlation between the stroke volume of the left ventricle and the amplitude and duration of the ventral motion of the aortic root [8] Even a comparison of the course of the carotid pulse curve or the apexcardiogram with the echocardiographic pattern of aortic root motion (Figs 2a and 2b) does not support the thesis that the stroke volume influences the movement of this vascular structure The tracing representing the ventral movement of the aortic root rises in fact constantly during the ejection period independently of the maximal aortic flow and volume changes expected during the upstroke of the carotid pulse curve to the percussion wave or to the e wave in the apexcardiogram The slope of the aortic root motion curve declines only slightly when the aortic valve has closed

reductions of resting membrane potential and of action potential amplitude and maximum velocity of phase 0 depolarization Action potential duration was increased as was the duration of the refractory period Impulses propagating in infarcted regions exhibited slowing of conduction and unidirectional block and reentry were demonstrated Enhanced automaticity was also observed It was postulated that these abnormal electrophysiological properties might form the basis of at least some of the ventricular arrhythmias which commonly complicate acute myocardial infarction

The effects of a drug lidocaine on the abnormal Purkinje fibers surviving in infarcted regions were subsequently studied by Allen and colleagues[21] who found that the drugs effects on such cells were different from what would have been predicted based on knowledge of its effects on normal cells Other investigators using a variety of drugs on cardiac tissues depressed by means other than acute myocardial infarction have also found that abnormal tissues may respond to drugs differently than do normal tissues[2, 23]

It is conceivable therefore that the abnormal Purkinje fibers surviving in infarcted regions might respond to digitalis differently than do normal fibers and that patients or animals with acute myocardial infarction might be susceptible to toxic arrhythmias on this basis In the present study we have tested this hypothesis using microelectrode techniques in vitro on tissue preparations obtained from infarcted canine hearts identical to those used by Friedman and Allen and their co workers[17, 18, 20, 21]

Methods

Myocardial infarction was produced in previously healthy adult mongrel dogs weighing 10 to 15 kilograms by ligating the left anterior descending artery under general anesthesia with intravenous sodium pentobarbital (30 mg/kg) using previously described techniques[17] The animals were allowed to recover from the anesthesia and then approximately 24 hours later the survivors were reanesthetized with sodium pentobarbital (15 to 30 mg/kg) and the hearts were rapidly excised and dissected in cooled oxygenated Tyrodes solution the composition of which has been described previously[1] The portion of the left ventricle comprising the anterior half of the interventricular septum and the paraseptal free wall with attached anterior papillary muscle was dissected free of other tissue and was pinned endocardial surface up to the wax base of a tissue bath (volume 50 ml) and superfused with Tyrodes solution at 20 ml/minute The dissection procedure has been described in detail elsewhere[7] The apical half to two thirds of the tissue preparations was infarcted but the basal portion including the tip of the anterior papillary muscle and the attached anterior division of the left bundle branch was invariably spared (Fig 1) Differentiation between normal and infarcted tissue was easily accomplished by gross inspec

Effects of ouabain on the electrophysiological properties of subendocardial Purkinje fibers surviving in regions of acute myocardial infarction

The belief that patients with acute myocardial infarction have enhanced susceptibility to the toxic effects of digitalis is widespread and is based primarily on animal studies which have consistently demonstrated that toxic arrhythmias develop at lower doses of digitalis in animals with experimental acute myocardial infarction than in normal animals [1] The clinical evidence supporting this concept is anecdotal and tenuous however [5-7] and there have been several clinical studies in which no evidence of enhanced toxicity of digitalis in patients with acute myocardial infarction was found [8-10] Nevertheless recent review articles and widely used current reference sources continue to indicate that patients with acute myocardial infarction have enhanced susceptibility to the toxic arrhythmias of digitalis [11]

The electrophysiological mechanisms responsible for arrhythmias occurring as a complication of digitalis toxicity have been extensively investigated using microelectrode techniques (for Reviews see references 14 and 15) A study carried out by Rosen and co workers is of particular interest since it correlated in vivo electrocardiographic evidence of digitalis toxicity with in vitro intracellular microelectrode recordings using an experimental preparation in which Purkinje fibers excised from a dog s heart were perfused in a tissue bath with blood from a living donor dog They demonstrated that the appearance of toxic arrhythmias in the donor dog s heart during ouabain infusion was associated with decreases in action potential amplitude resting membrane potential maximum rate of phase 0 depolarization and action potential duration of the simultaneously recorded Purkinje fiber transmembrane potentials and slowing of conduction velocity In some experiments automaticity due to phase 4 depolarization was enhanced In others automaticity was enhanced due to the occurrence of oscillatory afterpotentials (which Rosen and associates referred to as low amplitude potentials) Such oscillatory afterpotentials have also been observed by many other investigators in recent years and are now believed to play an important role in the genesis of digitalis arrhythmias [4, 15]

Most of the investigation into the cellular electrophysiological correlates of digitalis toxicity including the work of Rosen and associates cited above has been conducted on normal cardiac tissues In acute myocardial infarction however cellular electrophysiological properties are altered by the disease process The alterations which occur during the most acute phases of infarction are poorly understood at present but those which persist beyond 24 hours have been studied in detail [6] Friedman and coworkers [7, 8] found that canine subendocardial Purkinje fibers surviving in infarcted regions 24 to 72 hours after coronary artery ligation exhibited

by *measuring the distance between the onset of* the action potential upstrokes at the two sites Then with the transmembrane potentials being recorded continuously on moving film premature stimuli were introduced at progressively shorter coupling intervals after every eighth basic drive stimulus The intervals between the responses to the basic drive and premature stimuli at the proximal site (P_1P) and the distal site (D_1D) were determined until excitation of the subendocardial Purkinje fibers at the proximal site failed due to absolute refractoriness of those cells The effective refractory period was defined as the shortest P P interval at which conduction to the distal site was successful while the functional refractory period was the shortest D_1D_2 interval achieved The absolute refractory period of the cells at the proximal site was the minimum P_1P_2 interval achieved

In some experiments as the coupling interval of basic and premature stimuli (S S) was decreased the P P_2 interval decreased pari passu up to a point *then increased Because of the very* short distance between the stimulating electrode pair and the microelectrode at the proxima recording site we felt it was unlikely that th phenomenon was due to conduction dela between the stimulating and proximal recordin sites but was probably due to indirect activatio of the Purkinje fibers at the proximal site via th underlying muscle P_1P_2 and D_1D_2 interval recorded under such circumstances were dis carded In those experiments the effective refrac tory period was still the shortest P_1P_2 interval a which conduction occurred to the distal site bu the functional refractory period was the shortes D_1D interval achieved before latency develope between the stimulating and proximal recordin sites

3 Spontaneous activity While transmem brane potential was being simultaneously record ed from subendocardial Purkinje fibers at bot the proximal and distal sites the basic driv stimuli were abruptly terminated for approx mately 10 seconds The occurrence of sponta neous action potentials during the interruption o *driving stimuli* was noted if it occurred and th sequence of activation at the proximal and dista

tion—a method which has been validated by others.[17] For control studies anatomically identical tissue preparations were prepared from the hearts of normal dogs.

The superfusate was equilibrated with 95% O_2, 5% CO_2 and maintained at a temperature of 36 ± 1° C. Its potassium concentration was 4.0 mM in all experiments.

All preparations were stimulated extracellularly at a cycle length of 800 msec via Teflon insulated bipolar silver electrodes located on the non-infarcted tip of the anterior papillary muscle. Basic drive stimuli (S_1) were rectangular pulses 2 to 3 msec in duration and 1 to 2 times diastolic threshold in amplitude. For experiments in which conduction of premature beats and refractory periods were measured, premature impulses were delivered via the same electrode pair at selected intervals after S_1. The premature stimuli (S_2) were rectangular pulses 2 to 3 msec in duration and >5 times diastolic threshold. All stimuli were isolated from ground. Transmembrane potentials were recorded through glass microelectrodes filled with 3 M KCl with tip resistances of 10 to 20 megohms. The microelectrodes were coupled via a silver-silver chloride electrode to a preamplifier with high input impedance (1.5×10^{9} ohms) and capacitance neutralization.* The output of this preamplifier was displayed on oscilloscopes (Tektronix models 5433 and 5103N) and was photographed with oscilloscopic cameras (Grass model C4 and Tektronix model C5A, respectively). The maximum rate of depolarization of action potentials was determined by electronic differentiation as described by Bigger and co-workers.[24]

In all experiments subendocardial Purkinje fibers were impaled at two sites, a proximal one on the tip of the papillary muscle within 1 mm of the insertion of the false tendon carrying the anterior division of the left bundle branch and a distal site on the apical portion of the preparation below the insertion of the papillary muscle (Fig. 1). In all preparations the proximal site was within 2 mm of the stimulating electrode pair and was in normal tissue even in the tissue preparations with infarcts. The distal site was well within the infarcted region in infarcted tissue preparations, whereas in the non-infarcted preparations it was, of course, in normal tissue. All control observations were made after an equilibration period of at least 2 hours following dissection and mounting and during which the tissue preparation was driven regularly at a cycle length of 800 msec and was superfused as described above. Ouabain was then added to the superfusate in a concentration of 2.5×10^{-8} M and observations were repeated after exposure to the drug for between 90 and 120 minutes. The concentration of ouabain was lower than generally used in studies of toxicity. Preliminary experiments, however, had shown that conventional toxic doses of the drug caused the tissue preparations to rapidly develop spontaneous activity to such a degree that it was impossible to drive the tissue regularly and so to repeat during drug exposure the protocol which had been followed in the control period. By trial and error, a dose was selected which caused toxic manifestations to develop sufficiently slowly so that this problem was circumvented.

The experimental observations fell into three categories.

1. **Transmembrane resting and action potential characteristics.** Between five and 10 subendocardial Purkinje fibers were impaled consecutively at both the proximal and distal sites and photographic records were made of the transmembrane resting and action potential characteristics of each cell. At the two sites, all impalements were made within a 1 sq. mm. area. This procedure was repeated during exposure to ouabain. Data obtained from individual cells was pooled to give average values of the various transmembrane potential parameters for the two sites under control conditions and during drug exposure. These averaged data were then subjected to statistical analysis. It was necessary to make multiple impalements and use averaged data for analysis because movement of the tissue preparations, particularly during exposure to ouabain, rendered it impossible to maintain continuous impalements of single cells.

2. **Refractoriness and conduction.** Two cells were impaled simultaneously, one at each site. The two transmembrane potential recordings were displayed simultaneously on an oscilloscope. With the tissue being driven at a constant cycle length of 800 msec, photographs were made of the simultaneously displayed action potential upstrokes recorded at a rapid sweep speed (1 cm./5 msec.). Conduction time was determined

All values are mean ± S E M expressed in millisecond Results were obtained from experiments in five normal preparations in infarcted preparations conduction time was measured in 10 experiments and refractory periods in six The significance of the difference in mean values for a given parameter between normal and infarcted preparations is indicated by P Asterisks indicate the significance of the difference between mean values obtained before and during exposure to ouabain in a given type of preparation (= P < 0 05 = P < 0 01) NS = not significant

rations values for MDP Amp and V_m at the distal site were similar to those recorded at the proximal site Although values for APD_5 and APD_{100} were respectively 9 2% and 12 5% less at the distal site than at the proximal site these differences were not significant On the other hand in infarcted preparations the maximum diastolic potential and action potential amplitude were significantly reduced and APD 0 was significantly prolonged at the distal (infarcted) site when compared with the distal site in normal preparations The prolongation of APD_1 was sufficiently great that action potentials recorded at the distal site in infarcted preparations were longer in duration than those recorded at the proximal site the reverse of the situation observed in normal preparations This prolongation was due primarily to a decrease in slope of phase 3 of the action potential since APD 0 while slightly prolonged was not significantly so

In both types of preparation ouabain 2 5 × 10 M caused no change in MDP Amp APD_{50} and V_m at the distal site In normal preparations the drug also did not affect APD 00 but in infarcted preparations it caused significant further prolongation of APD_{100} by 6 8 ± 2 0% (mean ± S E M p < 0 01) Thus the discrepancy which existed under control conditions between the proximal and distal sites in the infarcted preparations with respect to APD was increased by the addition of the drug

2 Effects of ouabain on conduction and refractoriness (Table II) Under control conditions the conduction time of basic drive impulses from the proximal to the distal site was significantly longer in infarcted than in normal preparations Ouabain caused no change in normal preparations but in infarcted preparations the drug decreased conduction time by 22 ± 9% (p < 0 05) (Fig 2)

Prior to superfusion with ouabain premature impulses introduced near the proximal site conducted rapidly to the distal site in normal preparations and there was little increase in conduction delay as the coupling interval between the basic drive and premature impulses was progressively decreased This was presumably because action potential duration at the distal site was shorter than at the proximal site so that a premature impulse introduced at the proximal site would encounter progressively less refractory tissue as it propagated distally [18] For the same reason conduction block never occurred between the proximal and distal recording sites Thus there was no significant difference in these preparations between the absolute refractory period of cells at the proximal site the effective refractory period and the functional refractory period Following superfusion with ouabain 2 5 × 10 M for 90 minutes there was modest prolongation of all refractory periods but this achieved statistical significance only for the functional refractory period

In infarcted preparations unlike normal preparations premature impulses encountered progressively more refractory tissue as they propagated distally Thus as the coupling interval between basic drive and premature impulses was decreased conduction time of the premature impulses from the proximal to the distal site

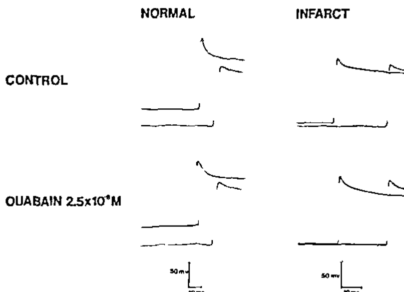

Fig 2 Effect of ouabain on conduction time between the proximal and distal recording sites in a normal preparation *(left panels)* and an infarcted preparation *(right panels)* The preparations were being driven at a cycle length of 800 msec In each panel transmembrane potential recordings are displayed from two Purkinje fibres one at the proximal and one at the distal site In the normal preparation the resting membrane potentials of the two cells have been separated vertically while in the infarcted preparation they have been superimposed In the normal preparation *(left panels)* conduction time between the two sites was 8 6 msec under control conditions After exposure to ouabain 2 5 × 10 M for 90 minutes the conduction time was virtually unchanged at 8 ? msec In the infarcted preparation *(right panels)* on the other hand conduction time decreased from 24.5 msec during the control period to 20 0 msec after exposure to the same concentration of ouabain for the same period of time

sites was also observed The transmembrane potential readings were carefully examined for the presence of oscillatory afterpotentials following the last driven impulse and also for the presence of phase 4 depolarization during and after cessation of pacing

In the experiments in which the effects of ouabain on refractoriness and conduction and on spontaneous activity were studied continuous impalements were not maintained throughout the experiments When a microelectrode became dislodged from a cell it was replaced in another cell within the 1 mm ^{2} confines of the proximal or distal site

Statistical analysis was carried out using Student s t test for comparing means of non independent samples to assess the significance of any change observed at a given site or in a given type of preparation (normal or infarcted) To compare data obtained from different sites or different types of preparation the t test for comparing means of independent samples was used A p value of less than 0 05 was considered significant

Results

1 Effects of Ouabain on Transmembrane Resting and Action Potential Characteristics

Proximal site (Table I) In both normal and infarcted preparations the proximal site was in a region of normal tissue Under control conditions there was no difference between infarcted and normal tissue preparations with respect to maximum diastolic potential (MDP) action potential amplitude (Amp) action potential duration to 50% and 100% repolarization (APD_{50} and APD_{100} respectively) and maximum upstroke velocity of phase 0 (V_{max}) of the action potential of subendocardial Purkinje fibers at the proximal site The addition of 2 5 × 10 M ouabain to the perfusate resulted in no significant change in any of these parameters

Distal site (Table I) In infarcted preparations the distal site was in the infarcted region while in normal preparations it was in normal tissue Prior to drug superfusion differences were observed at the distal site between the two types of preparation with respect to transmembrane resting and action potential characteristics In normal prepa

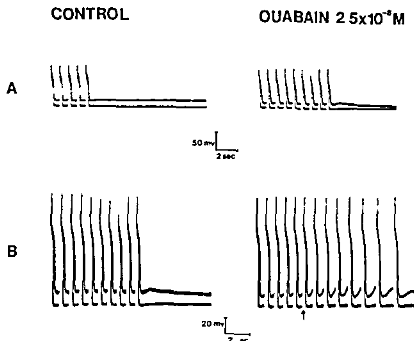

Fig 4 Ouabain induced oscillatory afterpotentials (OAP) *A* and *B* are from two different experiments conducted on infarcted tissue preparations In each panel the upper trace is the transmembrane potential recording from a subendocardial Purkinje fiber at the distal (infarcted) site and the lower trace is from a fiber at the proximal (normal) site In experiment A during control a stable resting membrane potential was attained and maintained at each site following cessation of pacing After exposure to ouabain a stable resting membrane potential again followed the cessation of pacing at the proximal site but a single low amplitude OAP was observed at the distal site following the last driven action potential In *B* there was a single low amplitude OAP at the distal site following the last driven response even during the control period Following exposure to ouabain the last driven action potential *(arrow)* was followed by several OAP of large amplitude These were initially of sufficient magnitude to bring the transmembrane potential to threshold resulting in action potentials which propogated from the distal to the proximal site The amplitude and rate of depolarization of the OAP progressively decreased and the cycle length progressively increased until there was failure to reach threshold Both during control and following ouabain the cell at the proximal site exhibited a stable resting membrane potential during phase 4

site where the slope was about 2 5 mv /sec

The eighth infarcted preparation exhibited a single oscillatory afterpotential at the distal site following cessation of pacing during the control period while at the proximal site a stable resting membrane potential occurred Following exposure to ouabain variable spontaneous diastolic depolarization was evident only at the distal site during pacing and when pacing was interrupted several oscillatory afterpotentials of sufficient magnitude to reach threshold and initiate action potentials occurred at the distal site These action potentials propagated to the proximal site where resting membrane potential remained stable during phase 4 (Fig 4*B*)

Discussion

The transmembrane resting and action potential characteristics of subendocardial Purkinje fibers and the functional properties of the subendocardial Purkinje fiber network which we observed under control conditions in both normal and infarcted preparations were generally similar to those which have been reported previously by other investigators [17 1] There were some minor differences however In normal preparations we found that although the duration of action potentials at the distal site was shorter than at the proximal site the difference was not statistically significant Others have found distal Purkinje fiber action potentials to be significantly shorter in duration than proximal action potentials [17 1 21] This discrepancy is probably due to the small number of experiments conducted on normal preparations in the present study since the mean values for APD_{50} and APD at both the proximal and distal sites were similar to those reported by others [17 19 1] In infarcted regions it has been previously reported that action potential duration is prolonged and resting membrane

increased and in two of six experiments there was conduction block between the two sites (Fig 3) In these preparations therefore the mean effective refractory period was longer than the absolute refractory period of the cells at the proximal site and the functional refractory period considerably exceeded the effective refractory period Ouabain caused prolongation of all three refractory periods the magnitude of which was statistically insignificant when compared with control values however (Fig 3)

3 Effects of ouabain on spontaneous activity *In five normal preparations the basic drive train* of impulses was abruptly interrupted for 10 seconds during the control period In each case following the response to the last driven impulse the fibers at both the proximal and distal sites attained and maintained a stable resting membrane potential during the entire 10 second interruption and no undriven action potentials occurred An identical response was observed in every preparation when pacing was interrupted after 90 minutes of exposure to ouabain 2.5×10^{-8} M

The response to 10 second interruptions of basic drive impulses was also studied in eight infarcted preparations In seven of these preparations a stable resting membrane potential was maintained at both the proximal and distal sites following the last driven action potential and no spontaneous activity was observed during the interruption of pacing during the control period After exposure to ouabain the response was the same in two of these preparations In two additional experiments although a stable resting membrane potential occurred at both sites during the suspension of pacing several spontaneous action potentials occurred at progressively longer cycle lengths after the last driven response Each undriven response resulted in activation initially at the distal site followed after a brief interval by activation at the proximal site indicating that the impulses probably originated within the infarct In two more experiments following cessation of pacing after exposure to ouabain no spontaneous action potentials occurred but a single oscillatory afterpotential was observed at the distal site while at the proximal site a stable resting membrane potential followed the last driven response (Fig 4A) In the seventh preparation a stable spontaneous rhythm with a cycle length of 80? msec and with activation at the distal site preceding the proximal site occurred after exposure to ouabain In this experiment stable phase 4 depolarization was evident at both sites after exposure to ouabain this was more marked at the distal site where the slope was approximately 5 mv/sec than at the proximal

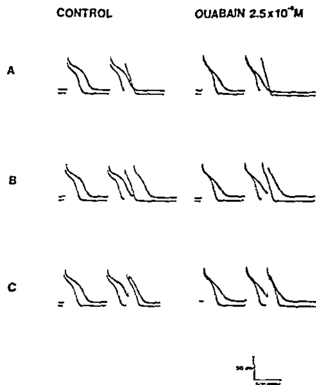

Fig 3 Effects of ouabain on the conduction of premature impulses in an infarcted tissue preparation In each panel the upper trace is recorded from a cell at the distal (infarcted) site and the lower trace is from a cell at the proximal (normal) site *The left hand panels* were recorded under control conditions while those on the *right* were obtained after exposure to ouabain 2.5×10^{-8} M for 90 minutes. The first two action potentials in each panel are responses to basic drive stimuli at a cycle length of 800 msec and the third action potential is the response to a premature stimulus. *A* shows the response to the earliest premature impulse which resulted in activation at the proximal site (absolute refractory period ARP) *B* shows the earliest premature response which conducted successfully to the distal site (effective refractory period ERP) and *C* shows the earliest obtainable premature response at the distal site to a premature impulse delivered near the proximal site (functional refractory period FRP) The ARP was 300 msec during control and 290 msec after ouabain The ERP was 320 msec under control conditions and 330 msec after ouabain These values differed from the ARP values because there was conduction block between the proximal and distal sites of the earliest premature responses both before and during exposure to ouabain *(panel A)* The FRP decreased from 400 msec during control to 380 msec after ouabain. Both under control conditions and during exposure to ouabain the FRP considerably exceeded the ERP because there was marked conduction delay of early premature responses (compare panel B with panel C) The changes in ARP ERP and FRP after ouabain were not significant.

velocity and failed to increase the functional refractory period in infarcted preparations unlike its effects in normal preparations It might have been expected that the prolongation of action potential duration in infarcted regions induced by ouabain would have resulted in prolongation of the functional refractory period of infarcted preparations of even greater magnitude than occurred in normal preparations The fact that this did not occur can be explained by the improvement in conduction which was observed Why conduction improved is not certain There are many possibilities including a change in the slope of the membrane responsiveness curve a reduction of the threshold voltage or alterations of the passive electrical properties of the Purkinje fibers making up the conduction pathway It cannot be explained by the observed effects of ouabain on transmembrane resting and action potential characteristics in the regions studied but since these characteristics of Purkinje fibers surviving in infarcted regions are very non uniform[17] and since we only studied minimally depressed areas it is also possible that ouabain had effects on transmembrane resting and action potential characteristics of more depressed parts of the conduction pathway which would result in improved conduction such as an increase in amplitude or V_m Finally, it is possible that phase 4 depolarization or oscillatory afterpotentials occurring in infarcted regions could facilitate conduction by bringing the transmembrane potential closer to the threshold potential[30]

In the present study there were also differences between normal and infarcted preparations with respect to the effects of ouabain on spontaneous activity While there was no effect on any of the normal preparations some form of spontaneous activity occurred in response to ouabain in six of the eight infarcted preparations studied Stable phase 4 depolarization was observed in one preparation more marked in the infarcted region than in the normal one and oscillatory afterpotentials were observed in the infarcted region in an additional three experiments In the other two experiments spontaneous activity was manifested by the occurrence of several unstimulated beats at progressively increasing cycle lengths following the cessation of pacing but the mechanism giving rise to these unstimulated responses was unclear since transmembrane potential was stable during phase 4 at both recording sites in these preparations

Enhancement of phase 4 depolarization and the development of oscillatory afterpotentials are two well recognized mechanisms by which digitalis may induce spontaneous activity in Purkinje fibers[14,15] The appearance of either of these phenomena has been reported to correlate well with the appearance of ventricular tachyarrhythmias in dogs given toxic doses of digitalis[16] The factors influencing the appearance of one or the other form of spontaneous activity are not well understood but Rosen and associates[31] found that enhancement of phase 4 depolarization tended to appear more readily in damaged tissue or in the presence of a low concentration of potassium in the superfusing solution whereas oscillatory afterpotentials tended to occur in normal tissues superfused with solutions having a potassium concentration of 4 to 5 5 mM[31] Our observations are in agreement with theirs in that in the minimally depressed areas we studied within infarcted regions (average resting membrane potential = 78 6 mv) and with superfusion with modified Tyrode s solution having a potassium concentration of 4 0 mM oscillatory afterpotentials were observed more commonly than enhanced phase 4 depolarization It must be noted that whenever oscillatory afterpotentials were observed they occurred only in the infarcted region and that when phase 4 depolarization occurred it was more marked in the infarcted than in the normal region

It is tempting to speculate on the possible clinical significance of our observations In theory the effects of ouabain on spontaneous activity could be responsible for the appearance of toxic arrhythmias in an infarcted heart at a concentration of the drug which would be well tolerated by a normal heart On the other hand the observed improvement of conduction caused by ouabain in infarcted tissue preparations without a concomitant change in the functional refractory period would in theory tend to prevent or abolish arrhythmias due to reentrant mechanisms in infarcted hearts[3] We feel however that any attempt to extrapolate our results in this manner must be made with extreme caution It requires the assumptions that subendocardial Purkinje fibers survive in regions of acute myocardial infarction in man as in dogs that the surviving fibers have similar electrophysiological properties in the two species in vitro and in vivo that the electrophysiological properties respond to digitalis in a similar manner and that the concentration

potential action potential amplitude and V_m are variably depressed when compared with anatomically similar regions of noninfarcted hearts[17, 19, 21] Our observations are in agreement although because of a large standard deviation the depression of V_m was not statistically significant

It should be noted that within the infarcted region we selected as the distal recording site an area in which resting membrane potential was not severely depressed and in which spontaneous diastolic depolarization was not evident when the preparation was being driven at a cycle length of 800 msec during the control period This was done for two reasons Firstly it has been reported previously that in 24 hour infarcts regions exhibiting severely depressed resting membrane potentials (i e less than −73 mv) do not maintain stable transmembrane resting or action potential characteristics over periods of several hours and hence would have been unsuitable for the present type of study[21] Secondly within the infarcted regions of different tissue preparations we wished to select areas with roughly similar baseline electrophysiological properties for study We recognize that the areas studied were not representative of the entire infarcted region in that they were undoubtedly less depressed than the infarcted region as a whole

It is well known that many hours of exposure to ouabain are required before a steady state is reached, and that inotropic effects occur long before any changes are demonstrable in transmembrane resting and action potential characteristics of normal mammalian ventricular myocardial cells and Purkinje fibers[2] The initial electrophysiological effect in normal Purkinje fibers has been reported to be prolongation of the action potential[2] and to our knowledge this effect has not been observed in normal mammalian Purkinje fiber preparations exposed to a concentration of ouabain as low as 2 5 × 10 M for less than 5 hours when the preparations have been driven at cycle lengths of 800 msec or more—i e under the conditions of this study Significant inotropic effects have been observed under these conditions however Thus we believe the effects of ouabain observed in this study correspond to the effects of a therapeutic concentration of the glycoside We recognize that the observations were made before a steady state was achieved and that more dramatic effects would probably have been seen after longer exposure to the drug

It is not surprising therefore that in the present study there was no effect of ouabain on transmembrane resting and action potential characteristics of subendocardial Purkinje fibers in normal preparations and in normal regions of infarcted preparations or on the conduction velocity and the effective refractory period in normal preparations Despite this there was significant prolongation of the functional refractory period of normal preparations The mechanism for this effect is not clear The functional refractory period depends on both the refractory properties of the individual cells forming the conduction pathway and on the many other factors which determine the velocity and safety factor of conduction along the pathway such as membrane responsiveness threshold for excitation and the passive electrical properties of the conducting cells We are not able to state which of these determinants were altered by ouabain or to what extent It is apparent however that prolongation of the functional refractory period of normal Purkinje fibers is a more sensitive electrophysiological indicator of digitalis effect than is prolongation of the action potential duration a fact which has not been reported previously

Within infarcted regions the effects of ouabain on surviving subendocardial Purkinje fibers differed from the effects on normal fibers in anatomically similar locations of normal noninfarcted hearts As in normal preparations the drug caused no change in the resting membrane potential or in the amplitude and rate of rise of the action potential upstroke of the abnormal fibers in infarcted regions and no change in the effective refractory period of the infarcted preparations It did however, cause significant prolongation of the action potential duration of fibers in infarcted regions As previously noted prolongation of the action potential duration has been reported to be the earliest effect of digitalis on transmembrane resting and action potential characteristics of normal Purkinje fibers The fact that ouabain under the conditions of this study caused prolongation of action potentials of Purkinje fibers in infarcted regions but not in normal regions indicates that the fibers in infarcted regions were more sensitive to this effect of the drug

Ouabain also caused an increase in conduction

of ouabain to which the tissues were exposed in our experiments corresponds to that to which tissues are exposed in vivo when a therapeutic dose of a cardiac glyceride is administered In addition it is possible that other factors such as autonomic nervous system activity might modify the direct electrophysiological effects of digitalis in vivo For example digitalis is known to exert a strong indirect effect on the normal heart by increasing vagal tone [14] and enhanced vagal activity has been reported to inhibit ventricular arrhythmias in acute myocardial infarction Acetyl choline the chemical mediator of vagal effects has been reported to abolish digitalis induced oscillatory afterpotentials in certain types of cardiac tissue [15] It is also important to note that the possible indirect effects of ouabain on the electrophysiological properties of cardiac tissues due to its effects on myocardial oxygen consumption have not been assessed in the present study Finally since our results were obtained from tissue preparations made after infarction had been present for 24 hours they may have little relevance to arrhythmias occurring in the first few hours after myocardial infarction [3] Thus while the present study has shown that the abnormal subendocardial Purkinje fibers surviving in regions of acute myocardial infarction in dogs have enhanced susceptibility to the direct electrophysiological effects of ouabain much further study is required before the clinical significance of this observation can be ascertained

Summary

We compared the effects of ouabain 2 5 × 10 M on the electrophysiological properties of minimally depressed subendocardial Purkinje fibers surviving in regions of acute myocardial infarction with its effects on subendocardial Purkinje fibers in adjacent normal regions and in anatomically identical regions of noninfarcted hearts Experiments were carried out in vitro on left ventricular tissue preparations dissected from the hearts of dogs 24 hours after coronary artery ligation and from normal canine hearts Ouabain had no effect on maximum diastolic potential action potential upstroke or V_m of Purkinje fibers in normal or infarcted regions It prolonged the action potential duration in infarcted but not in normal regions In infarcted tissue preparations ouabain increased conduction velocity and failed to alter the effective and functional refractory periods while in normal tissue preparations the drug did not affect conduction velocity or the effective refractory period but caused an increase in the functional refractory period Ouabain did not cause spontaneous activity in normal tissue preparations In infarcted preparations it resulted in spontaneous activity in six of eight preparations studied This was due to the development of oscillatory afterpotentials in three preparations and phase 4 depolarization in one in the other two preparations the mechanism was uncertain Thus Purkinje fibers surviving in infarcted regions are more sensitive than normal fibers to the direct electrophysiological effects of digitalis

The authors wish to thank Evelyne Stefaniszyn for her technical assistance and Louise McCrady for the preparation of this manuscript

spontaneous variability of T wa[illegible]

infused intravenously in each subject to increase the heart rate (HR) at least 30 beats/minute Infusion was adjusted to deliver 1 μg/mL of IS within 30 seconds Six athletes required a minimal dose of 5 μg to achieve the desired HR increase while two of them received 9 μg within 270 seconds None experienced any ventricular premature beats during IS infusion ECGs were recorded continuously up to third minute after the end of infusion and then at the fifth and tenth minute after infusion

Twenty minutes after the end of IS infusion when the ECG had indicated the return to control tracings atropine sulfate (AT) was administered intravenously in a single dose of 0 02 mg/kg of body weight within 30 seconds An AT test was performed in only seven of the eight subjects because one subject refused AT infusion The ECG was monitored continuously up to the third minute after the end of infusion and then at the fifth tenth fifteenth and twentieth minute after infusion

During pharmacological tests the VCG was recorded basally and when ECG tracings were made maximal effects of the drugs on the HR or T wave normalization were seen ECG tracings were accurately analyzed for T wave polarity and amplitude and for QT and QTc intervals[3]

Vectorcardiographic T loops in the frontal (FP) and horizontal planes (HP) were analyzed for (1) shape and sense of rotation (2) direction of maximum T vector ($\hat{V}max$ T) (3) QRS/T angle (A°QRST) and (4) length/width ratio (L/W)

Results

Resting ECG and VCG patterns *Resting ECGs of all athletes are shown in Fig 1 ECG features* are also summarized in Table I Four subjects had moderate and two others had marked sinus bradycardia

Four athletes fulfilled ECG voltage criteria of left ventricular hypertrophy (LVH) and two others had combined LVH and right ventricular hypertrophy (RVH)[illegible] Isolated T wave abnormalities were appreciable in five cases and were associated with the early repolarization variant (ERV)[illegible] in the remaining patients Two subjects had T wave inversion in the inferior limb leads (ILL) one in the left precordial (LPL) and the remaining patient in both limb and precordial leads

Case No 4 with MVP had a typical posteroinferior ischemia pattern[illegible] together with a distinct terminal T wave inversion in the right precordial leads (RPL) Case Nos 2 6 and 7 showed marked spontaneous variability of ECG tracings (see Fig 2) Resting QT and QTc interval were within normal limits in all cases

Resting VCG data are summarized in Table II

QRS/T angle in the frontal plane was abnormally wide in Cases 1 and 3 and in the horizontal plane in Cases 2 and 3 T loop rotation in the horizontal plane was counterclockwise (CCW) and the inscription of the efferent limb of the loop was slower than that of the afferent limb in all cases T loop shape in the horizontal plane showed a triangular pattern (see Figs 4 and 5) in four of six cases with negative T waves in the precordial leads and it was narrow in the remaining subjects In the three subjects with ERV[illegible] the ST vector oriented in the same direction as in the ECG tracings was appreciable Vectorcardiogram confirmed the left ventricular

T wave abnormalities in top ranking athletes effects of isoproterenol atropine and physical exercise

Paolo Zeppilli M D
Marco M Pirrami M D
Massimo Sassara M D
Riccardo Fenici M D
Rome Italy

Many authors have reported ST and T wave abnormalities as an unexpected finding in the electrocardiograms (ECGs) of top ranking athletes otherwise asymptomatic and fit for excellent performance Most of these authors agree about the benignity of these ECG anomalies especially when any evidence of organic heart disease is lacking[1, 3, 33, 39, 4, 4]
Recently[71] however we reported 12 cases of asymptomatic top level athletes with pseudoischemic T wave changes four of whom had asymptomatic mitral valve prolapse (MVP) and three who had an echocardiographic (ECHO) pattern of asymmetrical septal hypertrophy (ASH) Therefore the complete functionality of repolarization abnormalities in athletes is in our opinion at least questionable

In the present work a further eight top ranking athletes with repolarization abnormalities were investigated in order to ascertain

1 if ECG anomalies could account for any concealed organic heart disease

2 the mechanism underlying these ECG abnormalities in athletes

3 the diagnostic reliability of provocative tests with regard to these repolarization disorders

Materials and methods

Clinical and ECG data are summarized in Table I Eight top ranking athletes males aged between 17 and 37 years (mean 26 years) participating in different sports events particularly in the endurance type were referred to us by the Sports Medicine Institute of Rome (H Prof Venerando) for repolarization disorders Seven subjects were examined during their competitive season when they were well trained One subject (Case No 3) was examined 10 months after he had finished his competitive activity while he was still maintaining his physical fitness The follow up of this athlete continued for 12 years Another case (No 5) had a follow up period of 2 years All the subjects were completely asymptomatic Clinical examination and ECHO investigation were negative in seven of them One athlete (Case No 4) had auscultatory-echocardiographic features of mitral valve prolapse (MVP)[8] ECG tracings at rest and after pharmacological tests were made with a Hewlett Packard (HP) multichannel electrocardiograph Orthogonal Leads X Y Z and VCG loops were recorded with a HP vectorcardiograph (Moded 1507 A) using the Frank lead system

Resting ECGs and VCGs were taken 10 minutes after the athlete had been kept in the recumbent position ECG tracings were also recorded during and after rapid open hyperventilation (ROHV) Valsalva maneuver and standing

Subsequently a stress exercise ECG (EX) was performed in all athletes first by a 3 minute step test (Harvard) and then by bicycle ergometer maximal effort test On a second day after informed consent had been obtained a control ECG was recorded and thereafter a solution containing 1 μg/ml of isoproterenol (IS) was

hypertrophy diagnosis in Cases No 1 2 and 4

Provocative tests and exercise ECG The ECG modifications induced by the Valsalva maneuver and ROHV were not the same in individual subjects (Table III) Standing worsened ECG abnormalities in six of eight cases (75%) Step test exercise normalized the ECG in six cases while maximal effort (Fig 2) reverted the T wave in all subjects (100% of cases) All athletes achieved maximal HR and O uptake (VO max) adequate to their physical fitness No subject exhibited pathologic ST changes or ventricular arrhythmias during and after effort

Pharmacological tests Isoproterenol completely reverted the T wave (see examples in Figs 3 4 and 5) in six cases (75%) and reduced T wave inversion in the remaining two T wave modification was observed coincident with a combined increase of HR and a decrease of absolute QT interval Average absolute QT interval at which T

Fig 4 An 18-year-old professional soccer player with MVP In this case also isoproterenol infusion reverted T wave abnormalities. H = VCG horizontal plane

even more intriguing because of its legal implications Many authors observed spontaneous [1-5, 3, 5, 6] or provoked [3, 30] idiopathic T wave abnormalities in normal untrained persons with a higher percent incidence in Negroes (maximum 33 9%) [5, 6, 61] than in Caucasians (average 0 5%) [1, 6, 3, 54]

Epidemiological ECG screening performed in an unselected white population of 12 000 sportsmen participating in different physical activities and belonging to various competitive levels evidenced a percent incidence of T wave abnormalities (0 5%) similar to that of untrained people With regard to selected highly trained groups the percent incidence of major repolarization disorders ranges between 4 1 and 18% [1, 0, 1, 33, 39, 3, 53, 61, 6] This supports the opinion that T wave abnormalities are more frequent in top level athletes especially when they practice an endurance activity This observation suggested the hypothesis that intensive training could play a role in the pathogenesis of such repolarization disorders

T wave abnormalities may be produced by central nervous system disease [3] In addition T wave and QT interval modifications have been experimentally induced either by unilateral stimulation or by removal of stellate ganglia [3, 6] or by brief or prolonged cardiac nerve stimulation or catecholamine infusion Moreover changes in T wave amplitude or polarity were obtained in dogs by isoproterenol infusion into different regions of ventricular myocardium [3] Daoud and co workers [6] emphasized that isoproterenol reverts more than 90% of primary T wave abnormalities not due to pericarditis or ischemia while it does not normalize secondary T wave changes

Neither atropine infusion nor atrial pacing were effective in normalizing T wave polarity [9] T wave normalization after isoproterenol therefore should not be related only to HR increase but to a combination of a critical increase of HR and

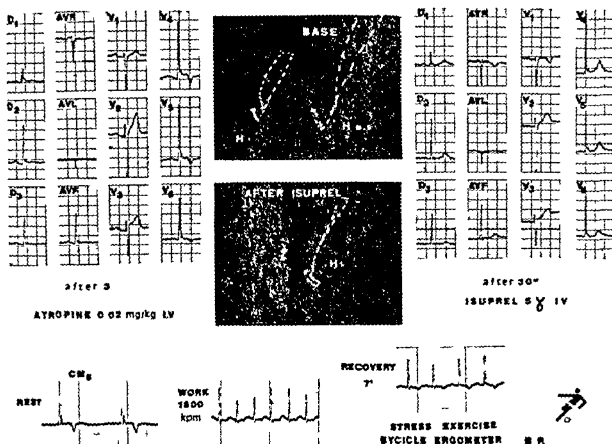

Fig 3 The same patient as shown in Fig Note complete normalization of T wave abnormalities after isoproterenol infusion and exercise H = VCG horizontal plane

Table III Effects of provocative tests exercise isoproterenol and atropine upon T wave abnormalities

Case	Valsalva	Hyperventilation	Standing	Exercise	Isoproterenol	Atropine
1	unchanged	unchanged	unchanged	normalized	normalized	unchanged

8	reduced	reduced	worsened	normalized	normalized	unchanged

wave normalization had been observed was 0 34 ± 0 04 sec with an average HR of 90 1 ± 14 1 beats/minute

Despite a greater increase of HR (average 105 8 ± 8 82 beats/minute) and a similar QT interval shortening (average 0 34 ± 0 03 beats/minute) AT infusion did not significantly change T wave amplitude or polarity in five cases reduced T wave inversion in 1 case and worsened it in another case

Discussion

ST and T wave abnormalities simulating pericarditis or myocardial ischemia in asymptomatic subjects without clinical or instrumental evidence of cardiopathies have long since represented a cardiological puzzle Moreover when these anomalies are encountered in athletes otherwise suited for excellent cardiovascular performance and who participate in intensive training and exhaustive competitions the problem is

particularly in females[15 19 41 0 5] mostly with benign prognosis[1 8 9 10 17 3 49 7] even if cases of sudden death and myocardial infarction were reported Since MVP had been discovered also in asymptomatic excellent athletes[* 1] a new problem arose about the significance of this finding Therefore this study was conducted to assess the advisability of allowing physical activity in these subjects

A more detailed discussion on this argument is beyond the limits of this work but we think in agreement with Barlow s opinion[9 1] that an asymptomatic athlete with MVP should be allowed to take part in his sport activity provided that he did not experience ventricular tachyarrhythmias during effort

Notwithstanding this great volume of studies the pathogenesis and significance of ischemic ECG changes in MVP still remain substantially obscure In our previous experience[1] T wave abnormalities in top ranking athletes with an ECHO pattern of MVP had their abnormalities reverted by maximal effort in three out of four cases This behavior was also observed in a further four subjects (unpublished data)

An isoproterenol test has been performed only in the athlete with MVP included in this study (Fig 4) who achieved a complete normalization of the T wave pattern Although a large number of cases should be investigated to ascertain the reliability of the isoproterenol test in athletes with MVP and an ECG ischemic pattern we suggest that the presence of repolarization disorders in asymptomatic and arrhythmia free athletes with MVP must be considered with caution and requires a more detailed investigation only when exercise and isoproterenol test do not revert these abnormalities

Summary

Eight cases of top ranking athletes with repolarization disorders" are reported All subjects were asymptomatic and were otherwise suited for excellent cardiovascular performances Seven athletes did not show any evidence of heart disease Seven had MVP (mitral valve prolapse)

Umprompted variability of ECG tracings was observed in three cases Both isoproterenol infusion (IS) and maximal physical effort (EX) normalized T wave abnormalities in 100% of cases while atropine (AT) was ineffective despite an increase in heart rate greater than that caused by IS The authors emphasize the usefulness of a combined use of the EX and IS tests in ascertaining the clinical significance of T wave changes in healthy athletes

A neurogenic mechanism is proposed by the authors for the pathogenesis of these T wave abnormalities This hypothesis may explain the umprompted variability of ECG tracings and T wave normalization after maximal physical effort and isoproterenol infusion

We thank Professor A Venerando of the Sports Medicine Institute of Rome for his continuing encouragement and support of our studies and for his assistance in the functional evaluation of the athletes included in this study We are also grateful to Mr Madeddu Alessandro for his assistance in preparing the tables figures, and the manuscript

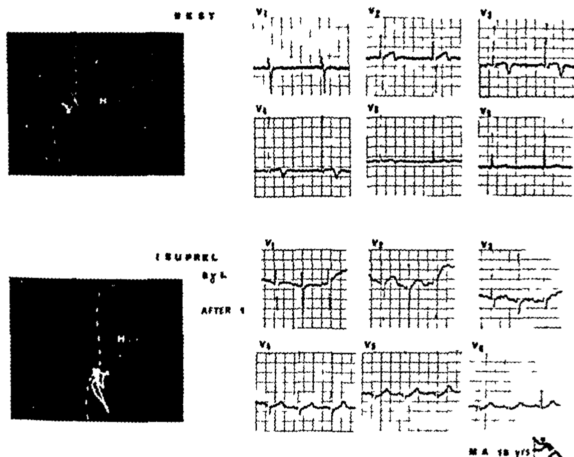

Fig 5 An 18-year-old canoeist (olympic rankin) The complete normalization of the T wave pattern after isoproterenol infu ion is clearly appreciable both on the ECG and on the VCG H = VCG horizontal plane

decrease of absolute QT interval duration caused by this drug Isoproterenol shortens monophasic action potential (MAP) duration due to the shortening of phase 2[31] This could explain the different effects of isoproterenol on normal and abnormal primary T wave changes In this regard we suggest that T wave abnormalities in top ranking athletes without clinical signs of organic heart disease if reverted by isoproterenol infusion or maximal physical effort should be considered functional We are in favor that such a diagnostic approach be routinely employed in these cases even if further investigation in a larger number of cases is required to define better the sensitivity and specificity of these tests

Pathogenesis of T wave abnormalities We have already suggested that primary T wave abnormalities in athletes could be neurogenic Prolonged physical training in fact is probably associated with both a decrease of resting vagal and sympathetic tone This could unmask in genetically predisposed athletes [5] a latent functional asymmetry of cardiac sympathetic nerves and induce inequality of ventricular repolarization resulting in T wave abnormalities[3] The normalization of ventricular repolarization obtained by both isoproterenol infusion and maximal effort could be explained as due to a uniform enhancement of sympathetic tone at high levels which overcomes functional asymmetry of resting cardiac sympathetic discharge

T wave abnormalities in MVP T wave abnormalities in subjects with MVP are a relatively common finding either as a typical posteroinferior ischemia" pattern or less frequently as diffuse T wave inversion [9, 33, 34, 35, 5] In addition patients with MVP have other ECG anomalies like atrioventricular conduction disturbances[5] and supraventricular and ventricular arrhythmias at rest and during effort [33, 37, 5, 49] Nevertheless MVP is a tremendously common finding in normal subjects

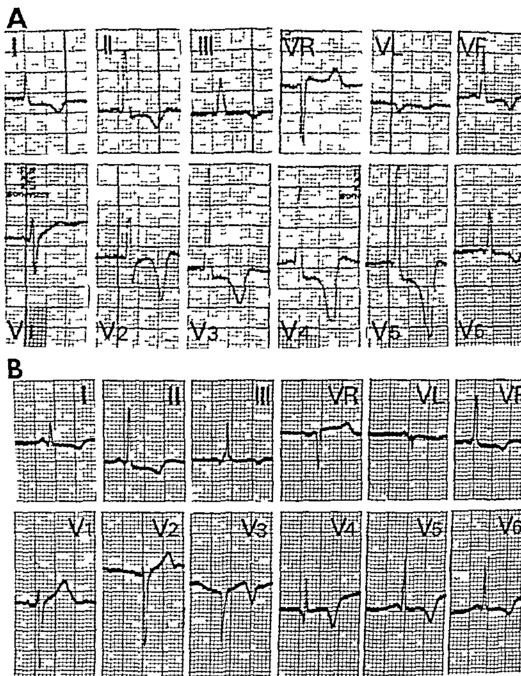

Fig 1 Pre *(A)* and postoperative *(B)* electrocardiograms Both tracings show a short PR interval (0 11 sec) New q waves (Leads V and V) are present after surgery

left ventricular angiogram was not different from that obtained preoperatively and selective coronary arteriography (Fig 3) revealed c mpl te release of the systolic obstruction of the LAD

Discussion

As far back as 1922 Crainicianu described for the first time the intramyocardial course of a segment of the left anterior descending coronary artery The frequency of this anomaly is relatively high as pointed out by Geiringer who found an incidence rate of 23% in his autopsy series Intramural segment occlusion is by far less common and it has been documented in about 0 5% of patients undergoing coronary arteriography

The ischemic nature of chest pain associated with significant systolic constriction of the LAD has been demonstrated in a group of subjects with milking effect and otherwise normal coronary arteries These patients showed myocardial lac

Case reports

Relief of angina by periarterial muscle resection of myocardial bridges

Amadeo Betriu M D
Julio Tubau M D
Gines Sanz M D
Jorge Magrina M D
Francisco Navarro Lopez M D F.A C C
Barcelona Spain

Systolic segmental narrowing of the left anterior descending coronary artery has been related to the presence of myocardial bridges Transient arterial constriction by muscle entrapment pro duces a characteristic milking effect which is easily recognized on angiography Patients with significant obstruction of the squeezed artery may develop ischemic chest pain It has been suggested that periarterial muscle resection to decompress the embedded vessel could be benefi cial in selected cases[1] Only five patients with this uncommon anomaly have been previously oper ated upon using such a technique but late follow up studies are lacking Two other cases have recently been reported in which arterial debridging was associated with revascularization procedures

This report documents a case of milking effect studied both before and 11 months after surgical repair of *two myocardial bridges* causing tran sient (systolic) occlusion of the left anterior de scending coronary artery

Case report

A 4 year-old man was admitted to the Hospital Clinico University of Barcelona in May 1976 for investigation of chest pain starting one year prior to admission Pain wa related to exertion and was relieved by nitroglycerin The patient was severely incapacitated (Class III NYHA) in spite of medical treatment with sedatives long acting nitrates and beta blocking agents Past history included typhoid fever (194) and two operations a gastrectomy (1943) and a chole cystectomy (1975) Cardiova cular examination revealed a soft S heart sound at the apex with no murmurs The heart rate was 60 beats per minute Blood pressure was 110/70 mm Hg Peripheral pulses were all palpable There were no signs of heart failure Chest x ray showed a normal sized heart The ECG (Fig 1) revealed sinus rhythm a short PR interval (0 11 sec) with notched QRS upstroke and no definite delta waves tall R waves (Leads V to V) and ST segment depres ion with deep inverted T waves in all leads Routine laboratory data were normal Transverse LV dimensions as well as wall motion and wall thickness were jud ed normal by echocardi ography An exercise test was discontinued because of chest pain and ST changes Double product at peak exercise was 1 760 mm Hg/minute (heart rate 110 beats per minute and systolic blood pressure was 160 mm Hg)

Combined right and retrograde left heart catheterization was carried out by the percutaneous technique No valvular or subvalvular pressure gradient was demostrated Left ventric ular end-diastolic pressure was moderately increased (24 mm Hg) Cardiac index was normal (3 L./min /M) A left ventric ular angiogram showed normal volumes and mass with an ejection fraction of 6 There was no mitral regurgitation Selective coronary angiography (Fig 2) demonstrated com plete systolic occlusion on two different segments of the LAD at its mid third The di tal vessel wa relatively narrow and short as it did not reach the apex The dominant ri ht coronary artery as well as the circunflex were entirely normal

Periarterial muscle resection was performed in June 1976 The mid third of the LAD was found to course close to the endocardium and its liberation resulted in right ventricular perforation. The defect was repaired and the postoperative course was uneventful despite the appearance of new q waves in Leads V and V (Fig 1) Since surgery the patient has remained asymptomatic of his chest pain A maximal exercise test performed in January 1977 was negative (double product 2 100 mm Hg/minute) A second hemodynamic study done 11 months after muscle resection showed normal LVEDP (10 mm Hg) and borderline cardiac index (2 5 L /min /M) The

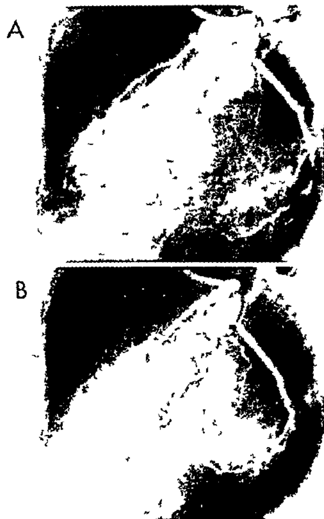

Fig 3 Diastolic *(A)* and systolic *(B)* frames showing release of obstruction following periarterial muscle resection

terial debridging and aortocoronary bypass grafting are probably not required in most patients with mural coronaries when arterial entrapment is not associated with fixed obstructions The lack of success of unnecessary combined procedures may be due to hemodynamic burden derived from flow competition

Summary

A 47 year old man presented with exertional angina Selective coronary arteriography showed complete systolic segmental occlusion of the left anterior descending coronary artery producing milking effect Permanent relief of symptoms was achieved by surgical excision of myocardial bridges Postoperative angiography performed 11 months later was normal Periarterial muscle resection should be considered in symptomatic patients with this rare anomaly

tate production and ST segment depression on the ECG during atrial pacing Thus ischemia seems to be triggered by a critical shortening of the diastolic filling period that compromises local O delivery

The intramural location of the LAD in the embryo points toward a congenital origin of this anomaly Although the delayed appearance of symptoms remains unclear it has been postulated that the acquisition of the milking effect could be secondary to progressive muscle growth and hypertrophy[5] Four out of 11 patients studied by Noble and associates had left ventricular hypertrophy and one of them was found to have a mild muscular subaortic stenosis Septal perforator compression has recently been documented in subjects with idiopatic hypertrophic subaortic stenosis[8] Slany and co workers reported a case in which histologic examination of excised muscle showed a marked thickening of fibers The finding of tall R waves in our case is in keeping with the diagnosis of hypertrophy but analysis of the angiograms revealed a normal left ventricular mass In addition echocardiographic assessment of both septal and posterior wall thickness was also normal Interestingly enough the LVEDP became normal after surgery and its dramatic reduction suggests in spite of a moderate fall in stroke volume an improvement in left ventricular compliance Reversal of ischemia suggested by decreased ST segment depression after surgery provides a satisfactory explanation for this finding

The presence of new q waves deserves comments Their appearance following revascularization procedures has been related to the occurrence of a myocardial infarction at the time of surgery an hypothesis substantiated by the finding of LV wall motion abnormalities in corresponding segments Since the second angiogram was unchanged infarction is unlikely Absence of infarction is also suggested by the regression of a previously elevated LVEDP On the other hand the LAD was not opened or hurt during the operation and it was found to be patent afterwards A logical explanation for the appearance of new precordial q waves is provided by the development of a septal focal block this form of segmental conduction disturbance being a consequence of the full thickness myotomy Pre excitation does not seem to account for the presence of new q waves as they were confined to Leads V_3

Fig 2 Preoperative left coronary angiograms (lateral view) in diastole *(A)* and systole *(B)* Note that the LAD becomes occluded *(arrows)* in systole

and V while the remaining leads did not show AV conduction changes In addition ajmaline administration failed to modify the atrioventricular conduction pattern

Prognosis of this anomaly is unknown Unexpected sudden death attributed to myocardial bridges has never been confirmed Disagreement exists in regard to their relationship with coronary atherosclerosis[7, 3] If one accepts that they play a role in the genesis of atheroma excision of bridges would undoubtedly be beneficial Release of obstruction may result in permanent relief of symptoms as demonstrated in our patient who remains free of angina 27 months after surgery Therefore it seems reasonable to recommend corrective surgery in disabled patients with significant systolic arterial constriction due to myocardial bridges Combined periar

Fig 1 High power magnification of an area of skeletal muscle showing infiltration by eosinophilic granular cells with areas of focal necrosis and nuclear anaplasia

Shortly after admission right ventricular pacemaking was established but the pacer failed to capture at times due to perforation into the pericardial cavity A permanent epicardial pacemaker was placed via a left anterior thoracotomy At thoracotomy numerous greyish nodules were found throughout the myocardium the pericardium the lungs and the pleura Four hundred milliliters of bloody pericardial fluid were drained

Biopsies of the myocardium pericardium lung and pleura were obtained Histological examination of the myocardial specimen revealed complete replacement of the myocardial tissue by granular cell tumor histologically similar to that obtained from the previous axillary and subcutaneous shoulder lesion Again no increase in mitotic activity was noted There was some nuclear anisocytosis but no anaplasia or necrosis The lung specimen showed a subpleural nodule extending into the pulmonary parenchyma composed of well differentiated granular cells

The patient was discharged from hospital 14 days later with good pacemaker function and was maintained on digitalis and diuretics until her death four months after discharge Autopsy permission was refused

Discussion

GCM is considered to be a rare tumor of soft tissue Nevertheless many cases were reported

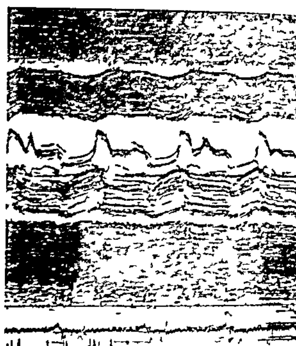

Fig 2 The echocardiogram shows marked thickening of the interventricular septum and the posterior left ventricular wall with diminution in the diameter of the left ventricular cavity There is a small posterior pericardial effusion

since 1926 when Abrikossof[3] described in detail the features of the tumor The term myoblastoma was questioned by some and many other terms have been proposed No agreement exists regarding the tumor s biological nature and origins Derivation from precursors of voluntary muscle cells viral factors response to parasitic infection perineural degeneration metabolic alterations lipoid thesaurismosis degeneration of the muscle fibers and derivation from Schwann cells have been suggested [4]

GCM is most frequently found in oropharyngeal and subcutaneous tissue but its occurence in a wide variety of sites has been well documented [1] It may occur in the eyelid breast colon ovaries or bronchus

It is believed that the tumor is generally nonmalignant and rarely metastasizing [6,11] although accounts of malignant forms have been reported [13,16] The tumor appears to be more frequent in women and blacks with a higher incidence in the third and fourth decades [1]

Strong and colleagues et al[1] reported three malignant lesions in their series of 95 cases one of which was cured by re excision Their statement that tumor size rapidity of growth, and invasion of adjacent structures may be more significant features in differentiation of benign from malig

Malignant granular cell myoblastoma with metastatic cardiac involvement: Case report and echocardiogram

George Kubac, M.D., F.R.C.P.(C)
Ian Doris, M.B., Ch.B., M.R.C.P. (U.K.), F.R.C.P. (C)
Milena Ondro, M.D.

Edmonton, Alberta, Canada

Granular cell myoblastoma (GCM) is a rare soft tissue tumor of which the vast majority are benign. Our case concerns a malignant variety which presented clinically as heart block.

The echocardiographic findings are described together with the histological findings in the primary tumor and the metastatically infiltrated myocardium.

Case report

The patient was a Caucasian female who was 43 years old at the time of the final admission.

Two years previously she had had a mass excised from the left deltoid muscle. The pathological specimen was a 7 by 5 by 4.2 cm mass consisting of firm grey brown tissue with admixed gritty white areas. The tumor was composed histologically of regular cuboidal cells with granular eosinophilic cytoplasm and small central nuclei. Most of the specimen was organized into small packages separated by connective tissue septae, but in one area there was focal necrosis with the adjacent cells showing some anaplasia. Included in this zone were a few atypical mitotic forms. In view of the paucity of mitotic activity, the diagnosis of a benign granular cell myoblastoma was made.

Approximately one year later the mass recurred with axillary lymphadenopathy. Repeat biopsy (Fig. 1) was performed. The specimen showed infiltration of the muscle by large masses of eosinophilic granular cells with focal areas of nuclear anaplasia and gigantism. In view of the course of the disease, the diagnosis was changed to malignant granular cell myoblastoma in spite of the persistent relative paucity of mitotic activity and cellular pleomorphism. Further investigations in search of metastatic disease were carried out including mammography, lung scan, liver and spleen scan, and bone marrow biopsy which were all normal.

Radiographs of the lumbar vertebrae showed sclerotic changes and the isotope bone scan showed widespread metastases in the pelvis, ribs, and spine.

On the final admission the patient was pale and thin on examination. Blood pressure was 90/[illegible]0. The heart rate was 25/minute. Jugular venous pressure was 12 cm H_2O and a left ventricular gallop was heard. The liver was smooth, soft, and slightly enlarged. No evidence of lymphatic enlargement was found.

The chest x-ray showed cardiomegaly with pulmonary hilar congestion. The CBC was normal. SGOT, LDH, and alkaline phosphatase were moderately elevated. The protein and immunoelectrophoresis were normal. ECG showed A-V block of third degree with effective heart rate of 28 per minute and an atrial rate of 80 per minute. Later, while monitoring the patient, long episodes of asystole (the longest 6 seconds) were demonstrated. Occasionally the patient was in sinus rhythm with a right bundle branch block and left anterior hemiblock. Complete left bundle branch block was transiently present on the ECG.

Echocardiography (Fig. 2). Standard M mode echocardiography was performed using commercially available equipment. Recordings were made with a 3.5 MHz transducer and recorded with a Honeywell strip chart recorder CRT Visicorder 1858.

The echocardiogram showed marked symmetrical thickening of the interventricular septum ([illegible] mm) and the posterior wall of the left ventricle (20 mm). No systolic change in thickness of the interventricular septum and only 2 mm further thickening of the posterior left ventricular wall occurred.

The left ventricular cavity was reduced on size with diastolic and systolic diameters of 34 mm and 30 mm., respectively. There was dilatation of the left atrium (15 mm). The EF slope of the anterior leaflet of the mitral valve was decreased (62 mm/sec.) A small posterior pericardial effusion was present. Based on these findings a diagnosis of infiltrative cardiomyopathy was made.

Infarct expansion: The "second event" after acute myocardial infarction

Kenneth J. Silverman, M.D.
Grover M. Hutchins, M.D.
Baltimore, Md.

Clinical course

This 57-year-old male was in excellent health until one day prior to admission when he first noted substernal chest pain like indigestion. He presented to the emergency room after the pain persisted for two hours. An electrocardiogram was normal (Fig. 1) and he was sent home. Thirty-six hours later he returned to the emergency room because of unremitting chest pain of increasing severity. The electrocardiogram demonstrated changes of an acute anterior myocardial infarction (Fig. 2) and he was admitted.

The past medical history was remarkable for excellent health. He had no previous cardiorespiratory symptoms and took no medications. His cardiac risk factors included a 70 pack-year smoking history and a positive family history with a brother succumbing to a myocardial infarction at age 55.

The blood pressure was 90/60 mm Hg, pulse rate 70 per minute and regular, respiratory rate 14 per minute. There was no jugular venous distention. Basilar rales were audible in both lung fields. The precordium was quiet with no palpable heaves. The point of maximal impulse was in the fifth left intercostal space in the mid-clavicular line. The first and second heart sounds were normal. No murmurs were heard but an S gallop was present. No hepatosplenomegaly or peripheral edema was present. The admission chest radiograph revealed bilateral interstitial infiltrates and minimal cardiomegaly. The admission electrocardiogram demonstrated changes of an acute anterior myocardial infarction with prominent ST segment elevation in Leads I, aV_L, and V through V_5 and ST segment depression in the inferior leads. New Q waves were present in Leads V_2 and V_3 that were not present in the previous day's electrocardiogram.

The chest pain was relieved with 3 mg of intravenous morphine sulfate. After an initial diuresis with a total of 60 mg of intravenous furosemide, he did well with no dyspnea, no further chest pain, no arrhythmias, good urine output, and a stable blood pressure of 110/70 mm Hg. The peak CK value was 850 I.U./L. This was obtained on admission with declining serial values over the first 24 hours of admission. The electrocardiogram evolved Q waves in Leads V_1 through V_5, persistent 2 to 3 mm ST segment elevation in Leads V through V_4 and lesser elevation in Leads I, aV_L, and V. There was minimal ST depression in the inferior leads. He did well until six days after admission when he complained of chest pain and shortness of breath. Physical examination revealed a blood pressure of 85/60 mm Hg and rales to the infrascapular border bilaterally. No rubs and no new murmurs were audible. An S gallop was present but no abnormal precordial pulsations were noted. The chest radiograph demonstrated a prominent bilateral perihilar alveolar and interstitial infiltrate and minimal increase in the cardiac silhouette from admission. The electrocardiogram demonstrated the evolution of an anterior myocardial infarction as well as acute ischemic changes with further ST segment elevation in Leads I, aV_L, and V through V and further depression in the inferior leads than was present on tracings taken since admission (Fig. 3). Serial CK values obtained at 4 hour intervals over the

nant types would seem to be borne out by our case

Moscovic and Azar[18] observed that in one third of the cases the onset of a second or multiple tumors was preceded by surgical or therapeutical manipulation of the primary lesion

Radiation therapy was generally disappointing[13] [?] but Hunter and Dewar[7] give it some merit and describe survival times two or three times longer in treated than in untreated patients

To our knowledge the role of chemotherapy has not yet been established

Primary cardiac involvement by GCM was reported by Roth and Spain in 1952 in a patient with congestive cardiac failure The tumor involved pericardial and myocardial tissues at the left atrial level above the atrioventricular sulcus

Disseminating metastasizing GCM with multisystem involvement including pericardium and myocardium was reported by Svejda and Horn and by Khanholkar[13] Our case is to our knowledge the third reported case of metastasizing GCM with cardiac involvement Our patient was a middle aged woman who twice had surgical intervention and had a primary muscular tumor A one year history of mild shortness of breath did not alarm her and it was the syncopal attack that brought her to a cardiologist s attention Complete A V block and episodes of asystole were the most dramatic events The echocardiogram with thickened ventricular walls and reduced interventricular septal and posterior left ventricular wall motion showed changes characteristic of infiltrative myopathy Associated were increased left atrial diameter and the presence of a pericardial effusion The causes of symmetrical septal hypertrophy such as left ventricular pressure overload were not present The patient s history together with the radiographic and isotope findings in the spine suggested metastatic disease The echogenic features could not be distinguished from the other causes of infiltrative cardiomyopathy

Morbid anatomical features strongly resemble the case of Khanolkar with the myocardium being sprinkled with numerous tumor nodules

Despite the extensive involvement by tumor the patient managed to survive the acute situation with A V block and she lived with a pacemaker for four months after her discharge from the hospital

Summary

A malignant form of granular cell myoblastoma originating in the shoulder gave rise to metastatic cardiac involvement causing infiltrative cardiomyopathy with heart block The patient survived four months with a permanent pacemaker The echocardiographic and histological features are described and the literature is reviewed Features shown on the echocardiogram are indistinguishable from other causes of infiltrative cardiomyopathies

next 24 hours remained within normal limits He was treated with intravenous morphine sulfate and furosemide with resolution of his symptoms and return of the ST segments to their position prior to this episode with persistent precordial elevation The next day he had another episode of chest pain and shortness of breath There were no associated ECG changes or CK elevation The chest pain was quickly relieved with morphine sulfate but despite furosemide and digoxin he continued to have slight shortness of breath and evidence of persistent pulmonary congestion on physical examination and chest radiograph After another episode of chest discomfort he was placed on nitroglycerin ointment which was well tolerated He had no further chest discomfort However 21 days after admission he unexpectedly developed ventricular tachycardia Despite repeated attempts at electrical cardioversion and extensive resuscitation efforts he was unable to maintain a pulse or blood pressure

Clinical discussion

DR KENNETH J SILVERMAN This case raises the common problem of a patient with a stable presentation and initially uneventful course following an acute myocardial infarction who rapidly and unexpectedly deteriorates with further chest pain or heart failure To maximize the patient s chance of survival the etiology of the patient s deterioration must be established quickly with a minimum of risk Extension of the myocardial infarction ventricular septal rupture ventricular free wall rupture papillary muscle rupture or dysfunction ventricular aneurysm formation pericarditis and pulmonary embolism are complications that must be carefully considered

Recurrence of chest pain onset of heart failure re evolution of ST segments and re evolution of CK are clues to myocardial infarct extension A study utilizing serial precordial ST segment mapping and serial CK values demonstrated evidence of infarct extension in greater than 50% of acute transmural anterior myocardial infarctions at an average of 5 8 days after admission The extension of myocardial injury may seriously compromise cardiac function and is a major determinant of mortality

Ventricular septal rupture complicates from 1% to 2% of all myocardial infarctions The infarct is usually transmural and the rupture usually occurs within the first week The presentation is often an abrupt deterioration in clinical status, with left ventricular failure a new pansystolic thrill and a loud pansystolic murmur [4] There may be further chest pain at this time Although the prognosis is poor death is often not sudden permitting time for diagnosis and treatment

Rupture of the free wall of the ventricle is a rare but catastrophic event with an average incidence of approximately 7% in autopsy series of patients with acute myocardial infarctions[5] Rupture is more common in patients suffering their first transmural infarction and may involve the anterior wall more frequently The most common presentation is sudden death usually within the first week after infarction [6] There are no characteristic features of the examination after rupture although findings consistent with cardiac tamponade may be present if there was slow leakage of blood and a blood pressure was maintained Sudden increase in amplitude of the T wave or reversal of previously inverted T waves has been described as a clue to the possibility of acute hemopericardium Some patients may experience repeated and prolonged chest pain which may be an indication of impending rupture with slow leakage of blood into the pericardium [7, 8]

Papillary muscle rupture has been noted at autopsy in as many as 5% of acute myocardial infarctions [9] It is not related to the size of the infarction most frequently occurring in infarctions that are relatively small in size and posterior in location The presentation is similar to ventricular septal rupture with dramatic deterioration in the patient s condition most frequently within the first week occasionally associated with chest pain [4] There is evidence of left ventricular failure and usually a loud pansystolic murmur but a prominent thrill is unusual Like ventricular septal rupture death is not sudden permitting time for diagnosis and treatment

Differentiating between ventricular septal rupture and papillary muscle rupture in a patient with sudden deterioration and a new systolic murmur can be difficult and may require insertion of a flow directed balloon catheter An increase in the oxygen saturation on passing from the right atrium to the right ventricle is evidence of a ventricular septal defect while prominent regurgitant V waves on the pulmonary capillary wedge tracing is evidence of mitral regurgita

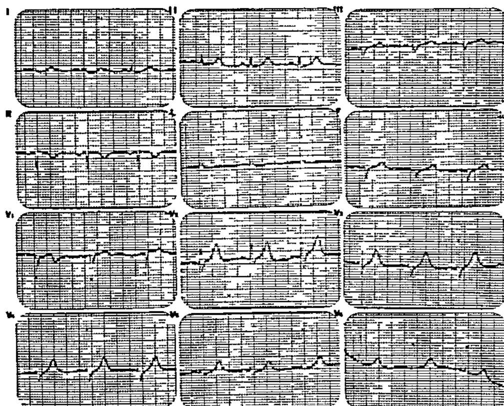

Fig 1 Initial 12 lead electrocardiogram is within limits with no acute ischemic changes

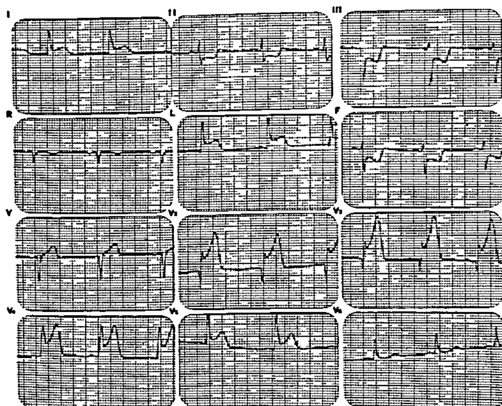

Fig 2 ECG taken on admission reveals changes of an acute anterior myocardial infarction

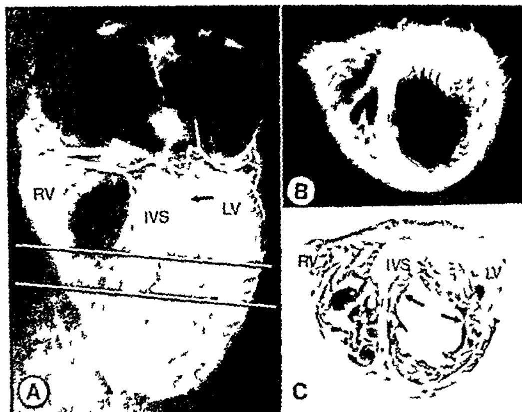

Fig 4 A through C A Postmortem coronary arteriogram The left anterior descending coronary artery is severely narrowed in its proximal portion (arrow) and its distal reaches are poorly filled. The apical region of the left ventricle is expanded B Radiograph of transverse section of the heart at the level shown by lines in A The infarcted anterior septal wall is markedly thinned compared to the surviving inferior lateral wall. C Cross photograph of the same heart section shown in B The infarct margins are at the arrows The expansion of the infarct is shown by the lateral displacement of the anterior papillary muscle complex

ing a transmural myocardial infarction Inspiration or motion often intensify the pain which is often exacerbated by lying flat and relieved by sitting up Splinting and dyspnea occasionally associated with pericarditis may be misdiagnosed as increasing congestive heart failure On auscultation a typical three component rub is often present but occasionally the rub may be heard only in systole or diastole and is misdiagnosed as a systolic or diastolic murmur or no rub is heard Low grade fever is usually present The chest radiograph may demonstrate an enlarging cardiac silhouette due to a pericardial effusion The electrocardiogram may have characteristic ST segment elevation but this is often not present Pericardial inflammation may predispose to arrhythmias

Non-cardiac causes of chest pain or hemodynamic deterioration must always be considered Pulmonary emboli may present with chest pain dyspnea increasing heart failure fever and tachycardia The chest pain of a dissecting aortic aneurysm is often localized in the posterior thorax but can present with anterior chest pain A murmur of aortic insufficiency and a widened mediastinum are useful clues Acute abdominal conditions must not be overlooked as an etiology of chest pain

Our patient's presentation emphasizes the importance of a careful history in the initial evaluation of a patient with chest pain The physical exam electrocardiogram and CK all may be normal Our patient suffered a large anterior transmural myocardial infarction The CK value probably peaked in the 36 hour interval between his initial emergency room visit and admission with the admission value of 800 IU/L on the descending portion of the CK curve

This patient did well until the sixth hospital day when he developed chest pain associated with pulmonary congestion a fall in his blood pressure and prominent electrocardiographic changes No

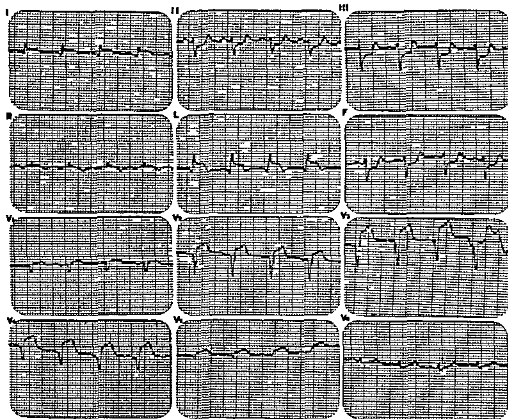

Fig. 3. ECG taken during pain on day 6 reveals evolution of anterior transmural myocardial infarction as well as acute ischemic changes with more pronounced ST segment elevation anteriorly and depression inferiorly than was present on tracings taken since admission.

ion. Cardiac blood pool scintigraphy may also differentiate between these two conditions. Insertion of a bolus of technetium labelled serum albumin into the antecubital vein or preferably into the pulmonary artery through a flow directed balloon catheter produces a dynamic nuclear angiogram. In the presence of a VSD the tracer appears in the right ventricle and pulmonary artery almost immediately after it appears in the left ventricle. If the physical findings are suggestive of cardiac tamponade, a flow directed balloon catheter may confirm its presence, but if the suspicion of ventricular free wall rupture is high, only cardiac catheterization with demonstration of leakage of dye on the ventriculogram can confirm and localize the tear.

The reported incidence of ventricular aneurysm following a myocardial infarction varies from 3.5% to 35% due to differences in diagnostic criteria. When defined as a protrusion of a localized portion of the external aspect of the left ventricle beyond the remainder of the cardiac surface with simultaneous protrusion of the cavity, the incidence is much closer to the lower figure. Aneurysm formation may occur acutely within the first week of a myocardial infarction or not until several months or years following infarction. Aneurysms most frequently occur in the anterior surface of the left ventricle following transmural anterior myocardial infarctions. Inadequate bed rest following infarction has been suggested to contribute to the development of ventricular aneurysms, but this has not been confirmed. Increasing congestive heart failure, serious arrhythmias, and recurrent embolic phenomenon are symptoms that should raise the possibility of aneurysm formation. Palpation may reveal an abnormal precordial pulsation. Chest radiographs may have abnormal contour of the left cardiac border including a localized bulge.[13] The electrocardiogram often reveals persistent ST segment elevation. Two dimensional echocardiography is a useful non-invasive technique for detecting aneurysms.

Pericarditis is a not infrequent cause of precordial or shoulder pain within the first week follow

new murmurs were audible no abnormal precordial pulsations were described and there was no re elevation of the CK He had two more episodes of chest pain not associated with electrocardiographic changes or CK elevation but with persistent pulmonary congestion He had no further chest pain after initiation of nitroglycerin ointment therapy but died suddenly 21 days after admission The absence of any murmurs or precordial thrill makes papillary muscle dysfunction or rupture and ventricular septal rupture unlikely causes of the cardiac decompensation Rupture of the ventricular free wall is equally unlikely for signs of cardiac tamponade should be present in a patient surviving for several days The persistent ST segment elevation suggests the presence of diffuse hypokinesis or an aneurysm A study of the natural history of ST segment elevation following acute myocardial infarction found that ST segment elevation persisting more than 2 weeks after myocardial infarction did not resolve over a 6 month follow up[11] It was associated with clinically more severe myocardial infarctions and left ventricular asynergy Other than ST segment elevation there were no other signs suggestive of pericarditis

This patient s clinical course is best explained by extension of his myocardial infarction As noted previously further myocardial necrosis has been noted in more than 50% of acute transmural myocardial infarctions at an average of 5 8 days after admission[1] After occlusion of a coronary artery the myocardial infarction in the distribution of the occluded vessel is not complete rather there is a zone of reversibly ischemic myocardium that is at risk for infarction[1] During the episodes of chest pain our patient was probably extending his infarct to include these areas of ischemic myocardium despite the absence of a re elevation of the CK It is not clear if the nitroglycerin ointment prevented further ischemic episodes or if the infarct has been completed with no further myocardium in jeopardy The persistent pulmonary congestion after the episodes of chest pain was secondary to extension of the myocardial injury further compromising cardiac function Studies are now underway to develop effective techniques of identifying patients with large areas of ischemic myocardium at jeopardy in the setting of acute myocardial infarction Interventions designed to preserve the ischemic myocardium might then successfully alter the course of patients such as the one under discussion

Autopsy findings

The heart examined after postmortem coronary arteriography and fixation in distension[1] demonstrated severe atherosclerosis with a 90% occlusion of the proximal left anterior descending coronary artery (Fig 4) The other coronary arteries had diffuse calcified atherosclerosis but no other obstructions greater than 50% of the lumen Histologic study of the region of maximum obstruction of the left anterior descending showed organizing thrombus situated over an ulcerated atherosclerotic plaque (Fig 5)

The region of heart supplied by the left anterior descending coronary artery had a massive transmural myocardial infarct (Figs 4 and 5) The infarct involved the epicardial fat and a portion of the right ventricle It extended from the anterior papillary muscle group to the junction of mid and inferior thirds of the interventricular septum The infarcted wall was markedly thinned compared to the surviving inferior and lateral wall

Histological study of the infarct showed it to be all of one age consistent with the clinical date of infarction The margins of the infarcted tissue adjacent to the surviving vascularized zones had well established granulation tissue formation The midportion of the infarct which was well removed from a vascular supply showed little evidence of resolution of the necrotic tissue (Fig 5) A small area of mural thrombus overlay the endocardium in the middle of the infarct but the majority of the endocardium showed thickening by connective tissue proliferation consistent with the infarct s age[1]

The lungs were congested and edematous Two small organizing infarcts with associated thromboemboli were present

Pathology discussion

DR GROVER M HUTCHINS The findings in the heart at autopsy show clearly that there had been but a single episode of myocardial necrosis The very large transmural anterior septal infarct was produced by thrombotic occlusion of the proximal left anterior descending coronary artery Usually in these cases the thrombus overlies an atherosclerotic plaque which has erosion or ulceration of its surface[19] The injured plaque surface and the plaque contents exposed to the circulating blood serve as a nidus for thrombosis Even in this patient where some time has elapsed since the acute event and organization and recanalization of the thrombus has occurred it is possible to

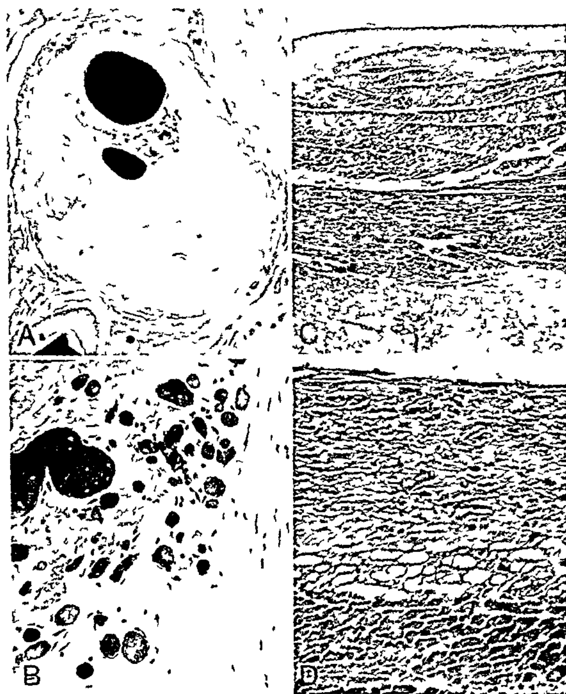

Fig 5 A through D *A* Transverse section of the left anterior descending coronary artery at the level of the arrow in Fig 4 A There are multiple channels of recanalization filled with black injection mass in the organizing thrombus (Hematoxylin and eosin original magnification ×30) *B* Channel of recanalization organizing thrombus and fibrous remnants of ruptured atherosclerotic plaque from the section shown in *A* (Hematoxylin and eosin original magnification ×300) *C* Transverse section of the anteroseptal transmural myocardial infarct from near its midportion The thinning of the wall is not explainable by reparative processes which are poorly developed in the infarct (Hematoxylin and eosin original magnification ×?0) *D* The endocardium shows marked thickening by mesenchymal cells and connective tissues in the area of the infarct The surviving subendocardial muscle is markedly vacuolated The infarcted muscle cells are eosinophilic and anucleate (Hematoxylin and eosin original magnification ×300)

new murmurs were audible no abnormal precordial pulsations were described and there was no re elevation of the CK He had two more episodes of chest pain not associated with electrocardiographic changes or CK elevation but with persistent pulmonary congestion He had no further chest pain after initiation of nitroglycerin ointment therapy but died suddenly 21 days after admission The absence of any murmurs or precordial thrill makes papillary muscle dysfunction or rupture and ventricular septal rupture unlikely causes of the cardiac decompensation Rupture of the ventricular free wall is equally unlikely for signs of cardiac tamponade should be present in a patient surviving for several days The persistent ST segment elevation suggests the presence of diffuse hypokinesis or an aneurysm A study of the natural history of ST segment elevation following acute myocardial infarction found that ST segment elevation persisting more than 2 weeks after myocardial infarction did not resolve over a 6-month follow up [11] It was associated with clinically more severe myocardial infarctions and left ventricular asynergy Other than ST segment elevation there were no other signs suggestive of pericarditis

This patient s clinical course is best explained by extension of his myocardial infarction As noted previously further myocardial necrosis has been noted in more than 50% of acute transmural myocardial infarctions at an average of 5 8 days after admission After occlusion of a coronary artery the myocardial infarction in the distribution of the occluded vessel is not complete rather there is a zone of reversibly ischemic myocardium that is at risk for infarction During the episodes of chest pain our patient was probably extending his infarct to include these areas of ischemic myocardium despite the absence of a re elevation of the CK It is not clear if the nitroglycerin ointment prevented further ischemic episodes or if the infarct has been completed with no further myocardium in jeopardy The persistent pulmonary congestion after the episodes of chest pain was secondary to extension of the myocardial injury further compromising cardiac function Studies are now underway to develop effective techniques of identifying patients with large areas of ischemic myocardium at jeopardy in the setting of acute myocardial infarction Interventions designed to preserve the ischemic myocardium might then successfully alter the course of patients such as the one under discussion

Autopsy findings

The heart examined after postmortem coronary arteriography and fixation in distension,[ ] demonstrated severe atherosclerosis with a 90% occlusion of the proximal left anterior descending coronary artery (Fig 4) The other coronary arteries had diffuse calcified atherosclerosis but no other obstructions greater than 50% of the lumen Histologic study of the region of maximum obstruction of the left anterior descending showed organizing thrombus situated over an ulcerated atherosclerotic plaque (Fig 5)

Pathology discussion

DR GROVER M HUTCHINS *The findings in the heart at autopsy show clearly that there had been but a single episode of myocardial necrosis The very large transmural anterior septal infarct was produced by thrombotic occlusion of the proximal left anterior descending coronary artery Usually in these cases the thrombus overlies an atherosclerotic plaque which has erosion or ulceration of its surface [15] The injured plaque surface and the plaque contents exposed to the circulating blood serve as a nidus for thrombosis Even in this patient where some time has elapsed since the acute event and organization and recanalization of the thrombus has occurred it is possible to*

recognize fibrous remnants of the atheroma in the organizing thrombus

The worsening of the patient s symptoms six days after the onset of the infarct is best explained by an expansion of the original lesion The topography of the heart as shown in Fig 1 is consistent with this interpretation The infarcted zone is markedly thinned compared to the adjacent surviving muscle thinned to a much greater degree than can be accounted for simply by the removal of necrotic muscle Also the relative positions of the anterior papillary muscle has been shifted to a more lateral position These two morphologic changes thinning of the infarct and altered topographic relationships can be accounted for by an expansion of the infarct

It is probable that the expansion occurs by an intramural tearing of the necrotic myocardium Ruptures of the ventricular wall septum or papillary muscle tend to occur at 4 to 6 days post infarction The sudden clinical worsening observed in this patient 6 days post infarction would correlate well with infarct expansion Extension of the infarct that is additional new myocardial necrosis was not observed

That the left ventricle develops worsened cardiac dysfunction as a result of infarct expansion even though no additional muscle has undergone necrosis may be secondary to the topographic changes The surviving inferior and lateral myocardium suffers a loss of curvature as a result of the expansion of the anterior septal region Effective ventricular function is dependent on an adequate thickness of myocardium arranged with appropriate curvature to translate wall tension into intracavitary pressure Infarct expansion tends to flatten parts of the functioning myocardium rendering them less able to generate pressure

Infarct expansion is of common occurrence in patients with large transmural infarcts ' In some instances the hypotension which accompanies the acute ventricular dilatation may lead to focal necroses on the margin of the infarct in the distribution of the obstructed artery These secondary lesions probably account for the serum enzyme elevations observed in some patients with this second event The electrocardiographic changes occurring at that time' may reflect simply an expanded area of infarct being presented to the precordial leads The evolution of infarct expansion originally observed in the hearts of patients studied at autopsy has now been confirmed by serial two dimensional echocardiographic studies A higher mortality rate was observed in those patients in whom there was a greater expansion of the infarct

Summary

This 57 year old man suffered a large transmural anteroseptal myocardial infarct After an initial stable period of several days he developed episodes of chest pain hypotension and congestive failure The left sided congestive failure persisted until death Study of the heart at autopsy showed that the worsened clinical state could be explained by expansion of the area of infarcted myocardium Infarct expansion may be regarded as a subtle form of myocardial rupture Intramural tearing of necrotic muscle may occur abruptly or insidiously and may lead to worsened cardiac function and symptoms and signs suggestive of new infarction The phenomenon of expansion should be distinguished from extension defined as additional myocardial necrosis since it may have important long term effects on the heart s topography and function

established working standards for vectorcardiography in 1975[5] but no real unanimity exists even now as to the best electrode *system*

To cardiologists not *primarily interested* in vectorcardiography these disagreements *on lead* systems have probably acted as a *deterrent to* clinical interest For that reason, this *review will* bypass completely a discussion *of the relative* merits of various lead systems—allowing *the read*er interested in that aspect to pursue *the appro*priate references on his own

A vectorcardiographic loop is *produced by* the simultaneous recording and combination *of* any two of the three leads (X plus Z X plus Y Y plus Z) These voltages are plotted from a central point usually on an oscilloscopic screen but in the case of the *direct writing* vectorcardiograph a moving arm *writes the loop* on an immobile piece of graph paper

Since most *electrocardiographic* information is found in the X (*left right*) *and* Z (posterior anterior) directions *it is not* surprising that the X Z combination (horizontal *transverse* or XZ plane) has the greatest *diagnostic power* The X Y combination is designated *as the frontal* plane, and the Y Z combination is designated as the *sagittal plane* which may be viewed from either the *right or left*

Since these loops *are a* plot of voltage against voltage elapsed *time must* be indicated by interruption of the *otherwise* continuous recording at predetermined intervals *such as* 1 2 2.5 5 or 10 msec each The *tracing is* interrupted in such a way that each *segment of the* loop has a distinct leading or trailing *edge*, *whose blunt* or pointed end indicates the directional *movement of the* loop as a whole

If the XYZ *leads* are recorded on magnetic tape the loops *may be generated* later from any set of simultaneous *complexes* and this taped information may *then be* subjected also to signal averaging noise *reduction* and computer analysis storage and retrieval

In its simplest form *vectorcardiography* has many disadvantages The *superimposition of* P QRS and T loops causes serious difficulty in evaluating *and timing* initial and terminal QRS forces However *the use of* gating circuits now available in the *current* commercially available units permits selective recording of isolated P QRS or T loop Thus the overlap problem has been largely eliminated

The *high gains* used in vectorcardiography readily introduce artifacts and 60 Hz interference especially in the Y axis These problems can be generally overcome by meticulous care of electrodes and cable tips proper skin preparation and careful grounding of the patient and the vectorcardiographic equipment

Location of the vectorcardiographic department far away from high voltage electrical equipment such as x ray machines and a comfortable bed for the patient (to decrease muscle movement) are also desirable Despite these precautions however occasional patients cannot be *recorded* without confusing interference

Bedside vectorcardiography is eminently possible and is performed in many institutions However it is even more often beset with technical problems as bedridden patients may be attached to other electrical equipment which causes interference and such patients are frequently uncooperative In addition vectorcardiographic equipment readily breaks down especially when moved about excessively Probably for these reasons vectorcardiographic study of acute ECG problems (such as acute myocardial infarction) are relatively few Nevertheless VCG s have even been recorded during exercise[4 6 7 8]

Vectorcardiograms are commonly recorded at very high amplification (5 cm to 40 cm per millivolt) The very high amplifications are used for study of P and T loops To the extent that the diagnostic power of vectorcardiography depend on this high amplification which facilitates precise time and voltage measurements equivalent results are entirely possible using standard leads with similar amplification

The development of the corrected lead systems has encouraged quantitative analysis of the XYZ leads and of the vectorcardiographic loops. These measurements may be made manually or by computer but the unique diagnostic power of the VCG lies in the directional and rotary characteristics of loops the so called phase relationships which result from the combination of voltages from the three lead axes

This review will be largely concerned with the qualitative description of P QRS and T loops in a variety of clinical situations rather than with the more quantitative aspects except for some simple quantitative criteria and measurements which can be derived manually As Witham has stated the analysis of a VCG by an experienced

undamentals of clinical cardiology

linical vectorcardiography in adults Part 1

win Hoffman M D
u Hyde Park and Far Rockauav N Y

he classic 12 lead electrocardiogram (ECG) emains the standard display method for surface ardiac electrical activity Another display the ectorcardiogram (VCG) despite an extensive terature developed over almost 30 years and the eady commercial availability of vectorcardio raphic equipment is employed in relatively few nstitutions Even when available it is usually mployed in only a small minority of cardiac atients

This review is directed to the cardiologist whose raining and interests may not have included ectorcardiography but who may now seek an utline of current knowledge literature and pplications of this technic

The author plans to keep constantly in mind he message implied in the paper by Eliot and ssociates entitled Loops for the Lost An Intro luctory Lesson for Vector Electrocardiographic Enjoyment (If not Proficiency and Accuracy)

Several excellent sources on vectorcardiogra hy are available in standard textbook form rogrammed or atlas formats and also in review rticles and audio cassettes The texts by Chou nd co workers and by Cooksey and colleagues nclude sections devoted entirely to pediatric spects emphasizing congenital heart disease Published symposia include sections on surface napping and computer analysis This review owever will be devoted to the current status of linical vectorcardiography in adult patients

The most simplistic approach to the VCG ssumes that all cardiac electrical activity (P QRS ST and T) originates from a single point (E) located in the anatomic center of the chest and conducted homogeneously to the surface In that situation an anatomically oriented electrode system would yield reliable X (left positive right negative) Y (foot positive head negative) and Z (posterior positive anterior negative) leads which would necessarily display all the data recordable by any surface electrode system

Unfortunately for vectorcardiographers the heart does not behave like a simple dipole gener ator immersed in a sphere filled with saline Accordingly a variety of lead systems have been described which either ignore or correct the inhomogeneities and compartmentalizations of the human heart

The corrected systems prescribe the location of seven or more electrodes modify the voltages obtained by means of resistances and then com bine the modified voltages in order to produce appropriate X Y and Z axis potentials The correction results in a three lead (XYZ) ECG which those surface voltages would represent in a 150 pound male subject with an idealized torso

Thus errors in correction are inherently present in large or small persons or in those with thoracic deformities and probably also in those with cardiac enlargement The basic assumptions also break down when the conductivity of the thoracic contents is greatly altered from the normal as in the case of emphysema

The Frank seven electrode lead system is almost universally used presently in the United States but serious workers have championed other systems have compared systems to one another and have even compared day to day variations and the effects of electrode placement in various interspaces and in various body posi tions and phases of respiration [3 5 3] A special committee of the American Heart Association

established working standards for vectorcardiography in 1975 [5] but no real unanimity exists even now as to the best electrode system

To cardiologists not primarily interested in vectorcardiography these disagreements on lead systems have probably acted as a deterrent to clinical interest For that reason this review will bypass completely a discussion of the relative merits of various lead systems—allowing the reader interested in that aspect to pursue the appropriate references on his own

A vectorcardiographic loop is produced by the simultaneous recording and combination of any two of the three leads (X plus Z X plus Y Y plus Z) These voltages are plotted from a central point usually on an oscilloscopic screen but in the case of the direct writing vectorcardiograph a moving arm writes the loop on an immobile piece of graph paper

Since most electrocardiographic information is found in the X (left right) and Z (posterior anterior) directions it is not surprising that the X Z combination (horizontal transverse or XZ plane) has the greatest diagnostic power The X Y combination is designated as the frontal plane and the Y Z combination is designated as the sagittal plane which may be viewed from either the right or left

Since these loops are a plot of voltage against voltage elapsed time must be indicated by interruption of the otherwise continuous recording at predetermined intervals such as 1 2 2 5 5 or 10 msec each The tracing is interrupted in such a way that each segment of the loop has a distinct leading or trailing edge whose blunt or pointed end indicates the directional movement of the loop as a whole

If the XYZ leads are recorded on magnetic tape the loops may be generated later from any set of simultaneous complexes and this taped information may then be subjected also to signal averaging noise reduction and computer analysis storage and retrieval

In its simplest form vectorcardiography has many disadvantages The superimposition of P QRS and T loops causes serious difficulty in evaluating and timing initial and terminal QRS forces However the use of gating circuits now available in the current commercially available units permits selective recording of isolated P QRS or T loops Thus the overlap problem has been largely eliminated

The high gains used in vectorcardiography readily introduce artifacts and 60 Hz interference especially in the Y axis These problems can be generally overcome by meticulous care of electrodes and cable tips proper skin preparation and careful grounding of the patient and the vectorcardiographic equipment

Location of the vectorcardiographic department far away from high voltage electrical equipment such as x ray machines and a comfortable bed for the patient (to decrease muscle movement) are also desirable Despite these precautions however occasional patients cannot be recorded without confusing interference

Bedside vectorcardiography is eminently possible and is performed in many institutions However it is even more often beset with technical problems as bedridden patients may be attached to other electrical equipment which causes interference and such patients are frequently uncooperative In addition vectorcardiographic equipment readily breaks down especially when moved about excessively Probably for these reasons vectorcardiographic study of acute ECG problems (such as acute myocardial infarction) are relatively few Nevertheless VCGs have even been recorded during exercise [63,6,9]

Vectorcardiograms are commonly recorded at very high amplification (5 cm to 40 cm per millivolt) The very high amplifications are used for study of P and T loops To the extent that the diagnostic power of vectorcardiography depends on this high amplification which facilitates precise time and voltage measurements equivalent results are entirely possible using standard leads with similar amplification

The development of the corrected lead systems has encouraged quantitative analysis of the XYZ leads and of the vectorcardiographic loops These measurements may be made manually or by computer but the unique diagnostic power of the VCG lies in the directional and rotary characteristics of loops the so called phase relationships which result from the combination of voltages from the three lead axes

This review will be largely concerned with the qualitative description of P QRS and T loops in a variety of clinical situations rather than with the more quantitative aspects except for some simple quantitative criteria and measurements which can be derived manually As Witham[1] has stated the analysis of a VCG by an experienced

observer requires only a few minutes and one or two simple measurements.

The normal QRS loop (references 2 to 40)

Vectorcardiographic notation can sometimes be confusing and many different kinds of terminology are used by different workers to describe the same thing. The simplest descriptive terms are *direction* and *rotation*.

Since the horizontal or transverse loop is derived from a combination of the X (left right) and Z (posterior anterior) axes, those four directions plus the designations *clockwise* or *counterclockwise* are really sufficient for almost all descriptive purposes.

Thus it may be simply stated that in the normal horizontal plane QRS loop the earliest forces are generally right and anterior followed by counterclockwise movement left and anterior which usually is completed by 30 to 35 msec.

Then the loop proceeds left and posterior where the maximum vectors are located and still with counterclockwise rotation. The loop finally returns to the E point after terminal rightward forces are commonly inscribed posteriorly. The time dashes are frequently close together indicating slight conduction delay for the first 20 msec and the last 30 msec of the QRS loops. The duration of the loops in the normal usually does not exceed 100 msec. However with tape recording techniques and high amplification occasional normal values up to 120 msec have been observed.[4]

The maximum voltage in the horizontal plane rarely exceeds 2.0 millivolts in the normal. Standardization is usually inscribed as a 1 or 0.5 millivolt equivalent adjacent to each loop submitted for interpretation.

Inspection of a few normal vectorcardiograms in any of the general references will permit even a novice to familiarize himself quickly with normal loops. In the frontal (X Y) reference plane the directions are of course left right and inferior superior and the rotations are again clockwise or counterclockwise. In this plane however the normal rotation varies according to the direction of the major QRS vector. If the QRS loop lies along the X axis or close to it ("horizontal" position) the loop will normally exhibit counterclockwise rotation. On the other hand if the major QRS vector lies more or less along the Y axis ("vertical") position the normal loop will exhibit clockwise rotation. In the intermediate position roughly at +45 degrees in the frontal plane the loops are commonly rather narrow and may exhibit figure of eight shapes or may display clockwise or counterclockwise movement. An important variant of normal is frequently seen in the frontal plane especially in young women of slender body build. The major QRS vector may be directed along or even to the right of the Y axis producing a "vertical" position. The initial forces are commonly leftward rather than to the right and the entire loop is inscribed clockwise. The initial leftward forces are above the X axis so that Q waves are inscribed in scalar Lead Y and also in Leads 3 and F of the conventional electrocardiogram. This loop is similar in some respects to loops seen in inferior divisional block and in right ventricular hypertrophy. It may also be confused on occasion with the frontal loop of inferior myocardial infarction.

When the vectorcardiographer has described the horizontal and frontal loops he has utilized information from all three (X Y and Z) axes and theoretically no additional information can be derived from the last combination (Y Z)—the sagittal reference plane.

It naturally follows from the above considerations that when the sagittal reference plane is viewed from the right the initial forces will be anterior the major forces posterior and the rotation will be clockwise.

The value of recording loops in all three projections lies in the possibility that initial or terminal forces may be perpendicular to one of the reference planes and therefore not be recorded well if at all in that particular plane.

The vast majority of vectorcardiographic interpretations however can be made from inspection and measurement of the horizontal and frontal loops only—the sagittal reference plane being used for confirmatory purposes.

Although variations in QRS loop magnitudes have been described related to sex race and body build these variations are rather small. However in an occasional case it is important to realize that voltages tend to be smaller in women and larger in males especially blacks. Greater voltage variations are encountered in the vectorcardiograms of infants children and adolescents.[37, 3] Here the relative thinness of the chest wall plays an important role. The normal voltages for the various reference planes at different ages have

tal plane and generally exhibits counterclockwise rotation.[1] These T loop abnormalities as well as other varieties of repolarization disorders will be discussed in a separate section devoted to T loops.

Right ventricular hypertrophy (references 2 to 16, 56 to 74)

As has been discussed above, the normal QRS loop represents a "levo" vectorcardiogram owing to the normal domination of QRS activity by the left ventricle. It is not surprising, therefore, that in only very advanced right ventricular hypertrophy will the resulting QRS loop be oriented completely anterior and rightward—the electrical *position of* the right ventricle. In lesser degrees of right ventricular hypertrophy, a shift of the QRS either anteriorly or to the right occurs, but usually with preservation of some leftward QRS forces and with preservation of the counterclockwise rotation in the horizontal plane, which is characteristic of the normal left ventricular QRS loop.

These several features have become the basis of Chou and associates' classification of right ventricular hypertrophy. The classic or severe type, in which the loop is oriented both to the right and anterior in the horizontal plane and with reversal of rotation from counterclockwise to clockwise, has been designated as Type A. This variety is seen commonly in congenital heart disease in children, especially with pressure overloads as in pulmonic valve stenosis. When seen in an adult, *for example*, with cor pulmonale or mitral stenosis, one may be sure that the pulmonary artery pressure is extremely high. Type B right ventricular hypertrophy is characterized by an anterior addition of QRS forces, usually in the first half of the loop and with little or no addition of rightward forces. This results in an anterior counterclockwise QRS loop in the horizontal plane which is oriented to the left and anterior of the E point. In general, Type B RVH loops are encountered with milder degrees of right ventricular hypertrophy than Type A. In the Type C variety, anterior forces are minimal and the major alteration from normal is the addition of rightward forces, usually in the middle and terminal portions of the QRS. The normal counterclockwise rotation is preserved, and of course the addition of rightward forces decreases the maximum leftward voltage while the maximum rightward voltage increases, especially terminally.

This variety of QRS loop is frequently seen in acquired right ventricular hypertrophy in adults, especially in cor pulmonale and in mitral stenosis.

Although many published quantitative criteria are available for the identification of right ventricular hypertrophy, the following have proven to be of the greatest value in the author's experience:

1. Maximum rightward voltage of 1.0 millivolts or greater.
2. The left/right millivolt ratio less than 1.0.
3. The percentage of loop area in the right posterior quadrant of the transverse plane exceeds 20% of the total QRS loop area.
4. The anterior and rightward QRS loop area in the transverse plane exceeds 70% of the total area.
5. The QRS loop area in the right inferior quadrant of the frontal plane exceeds 20% of the total area.

As in the case of left ventricular overloads, attempts have been made to identify diastolic or systolic overloads on the basis of various VCG patterns. Two decades of experience have convinced most workers that such separations are simply not possible. In the case of pure pressure overload on the right side, there is little doubt that the rightward voltages bear a close relationship to the right ventricular systolic pressure and may be predictive of pulmonic valve gradient in cases of pulmonic valvular stenosis. However, in the frequent combinations of right ventricular obstruction with other lesions such as shunts, attempts at pressure estimation are often misleading.

The greatest difficulties in the vectorcardiographic diagnosis of right ventricular hypertrophy lie in two special circumstances:

1. The counterclockwise anterior horizontal loop which may resemble the loop of dorsal myocardial infarction or a very similar loop seen commonly in persons without heart disease of any kind. This problem will be discussed in a subsequent section as "anterior conduction delay."
2. The problem of loops which have some characteristics of right ventricular conduction delay (terminal slowing oriented to the right, either anterior or posterior) but with significant anterior or rightward orientation of major QRS vectors. Here the separation between a pure conduction delay and conduction delay asso-

angle the distal half of the QRS loop may exceed in area the proximal half and the time at which maximum QRS forces are achieved may be delayed [1]

These vectorcardiographic features are particularly valuable when voltage criteria for left ventricular hypertrophy are not satisfied Although values of 2 0 millivolts or greater in the horizontal plane are strongly suggestive in adults of left ventricular hypertrophy such voltages are commonly not achieved even when the scalar 12 lead ECG satisfies standard voltage criteria This discrepancy probably results in the Frank system from the attenuation of uncorrected torso voltages by the resistances employed especially at the apical or V_4 position which frequently is the site of the greatest voltage found on the torso Attenuation may also result when the cube or tetrahedral lead systems are used owing to the remoteness of the electrodes from the precordium

Despite the lack of sensitivity to decreased voltage the other QRS loop characteristics of LVH described above are frequently valuable guides to diagnosis However it must be admitted that as far as voltage criteria are concerned the scalar 12 lead ECG is a more sensitive detector of left ventricular hypertrophy than is the vectorcardiogram

Caution must be used in interpreting high voltage QRS loops in children or adolescents The thin chest wall and relatively large heart frequently result in high QRS voltages in the absence of anatomic abnormality The over all QRS duration in left ventricular hypertrophy may frequently reach 120 msec but the rotational characteristics do not resemble left bundle branch block and the time dashes are evenly spaced quite dissimilar from the clustering effect seen in bundle branch disturbances

Several studies have correlated hemodynamics and left ventricular mass with vectorcardiographic measurements [5]

Ishizawa and associates correlated the vectorcardiogram with left ventricular mass determined angiographically while Bennett and Evans made similar correlations with echocardiographic measurements

In both studies maximum vectorcardiographic voltages especially in the horizontal plane correlated *extremely* well with left ventricular mass determined as mentioned above Ellison and Restieaux have reviewed the correlations between right or left ventricular hemodynamic load and the vectorcardiogram while Yankopoulous and associates[3] made similar studies in 257 patients with clinical aortic valvular disease

Again although many vectorcardiographic measurements were used the most effective were horizontal plane or spatial voltages and the R wave peak time in lead X

However Yankopoulous and colleagues confirmed the difficulty of finding criteria which would separate systolic overload left ventricular hypertrophy (aortic stenosis) from volume overload left ventricular hypertrophy (aortic regurgitation)

No reliable criteria enabling separation were found and it seems reasonable at this stage of knowledge to be satisfied with the diagnosis of an abnormal QRS loop indicative of left ventricular hypertrophy or left ventricular overload without specifying whether the ventricle has been subjected to increased volume or pressure work An additional qualitative characteric of left ventricular hypertrophy loops is the tendency for the normal initial anterior rightward forces (found in approximately 85% of normals) to be replaced by initial anterior leftward forces This characteristic is present in approximately 60% of patients with hypertension or aortic valvular disease No completely satisfactory explanation for this initial shift has been established although several have been proposed In the author s view simple early leftward posterior addition would naturally reduce or even eliminate the normal right anterior or initial forces and could account for the observed changes without invoking anatomical shifts of the interventricular septum or septal fibrosis or infarction

The frontal QRS loop in left ventricular hypertrophy is most commonly located inferior to the X axis and to the left of the E point Thus an abnormal superior axis is not a feature of left ventricular hypertrophy However the loops commonly lie close to the X axis and in this position as in normal loops occupying similar positions the rotation is counterclockwise The voltage criteria for hypertrophy in the frontal reference plane is also approximately 2 millivolts especially if the patient is over 40 years of age In younger patients a value of 2 4 millivolts should be exceeded in order that left ventricular hypertrophy be diagnosed

The T loop in left ventricular hypertrophy is oriented to the right and anterior in the horizon

rior forces will include associated right ventricular hypertrophy associated dorsal infarction or associated anterior conduction delay [9,10] and this will be discussed in a subsequent section devoted to prominent anterior forces

When the horizontal QRS loop suggests right ventricular hypertrophy because of prominent anterior forces (Type B) or because of anterior and clockwise rotation (Type A) [78] and the frontal loop does not exhibit the expected clockwise rotation but is instead inscribed counterclockwise associated left ventricular hypertrophy should be considered [9,8] In these instances if the counterclockwise rotation in the frontal plane is associated with an abnormal superior axis right ventricular hypertrophy with associated superior divisional block or its equivalent would be the preferred diagnosis

Ventricular septal defect in infancy is an interesting model of biventricular hypertrophy with varying degrees of right ventricular enlargement depending upon the restrictive characteristics of the septal defect In a non restrictive defect the right ventricle operates against systemic pressure and the most severe type of right ventricular hypertrophy results All gradations of relative right and left ventricular hypertrophy are thus possible in this entity Riggs and associates [4] have described vectorcardiographic patterns in the horizontal plane which suggest the presence of non restrictive defects As one might expect these are the patterns of more severe right ventricular hypertrophy In one such pattern the horizontal loop is completely anterior rightward and entirely clockwise while in the second pattern suggesting a non restrictive defect only the mid portion of the QRS loop exhibits counterclockwise rotation with the entire loop anterior to the E point the significant terminal rightward forces and a terminal appendage are inscribed clockwise

The scalar electrocardiographic equivalent of the Katz Wachtel phenomenon is found in the vectorcardiographic loop in the horizontal plane characteristic of left ventricular hypertrophy but with prominent anterior forces exceeding 0 6 millivolts The scalar precordial leads in such instances would display very large biphasic complexes and are thus suggestive of biventricular hypertrophy

Gamboa and [illegible] have compared the vectorcardiogr[illegible] orthogonal electrocardiograms of 87 patients [illegible] necropsy evidence of biventricular hypertrophy to both normals and to patients with left ventricular hypertrophy or right ventricular hypertrophy They have published useful scalar criteria for separating th BVH cases from normal and for separating BV cases respectively from LVH or from RVH

Prominent anterior QRS forces (references 85 to 101)

So far in this review changes in voltage ar axis shift have been described as resulting onl from hypertrophy of the right or left ventricle However as mentioned earlier in the discussio entirely similar axis shifts may occur as a result subtraction (as infarction) or from conducti delay—in which the QRS axis shifts in the dire tion of the impaired conduction One of the ear promises of vectorcardiography was the appare ability to recognize true posterior or dorsa infarction [85,87] In such cases the subtraction posteriorly directed QRS forces would result in anterior shift of QRS loops Although the prec dial scalar leads in such cases would continue show R waves as they do normally the change precordial leads might be limited to a broadeni of the R waves in Leads V_1 V and V contrast the vectorcardiographic loop wo show a major shift in direction anterior and the left of the F point

As vectorcardiography developed and beca more quantitative with the introduction of c rected lead systems actual quantitative crite were proposed for the recognition of true posterior infarction [87] when prominent anterior loops were encountered and were unaccompanied by evidence for inferior or lateral infarction—in which cases of course the diagnosis of adjacent dorsal infarction was relatively easy

These concepts were proven incorrect with the advent of coronary arteriography and by contrast ventriculography With these techniques it became apparent that many patients presenting with prominent anterior QRS loops had either perfectly normal coronary arteries or inappropriately placed coronary disease—most frequently in the left anterior descending artery Clearly some other explanation was needed

These difficulties were recognized by several authors notably by Kennedy and associates and by Ha and colleagues who pointed out that the prominent anterior horizontal QRS loops of patients with proven dorsal infarction were in

ciated with right ventricular hypertrophy may be difficult indeed The classic problem is presented by patients suspected of atrial septal defect and who present with scalar ECG s manifesting RSR complexes in Lead V and a picture of incomplete right bundle branch block In such cases a clear separation even by vectorcardiogram between RVH and pure right ventricular conduction delay may be difficult In the absence of terminal conduction slowing and with loops oriented largely anterior to the E point a diagnosis of moderate RVH as seen in atrial septal defect is warranted However when only terminal conduction delay is present so that pure right ventricular conduction defect must be diagnosed atrial septal defect is by no means ruled out

The problems attending the diagnosis of right ventricular hypertrophy in the presence of right bundle branch block will be dealt with in the section on right bundle branch block

The frontal QRS loop in right ventricular hypertrophy of either Types A or C is oriented inferior to the E point with clockwise rotation and prominent terminal forces to the right The Type B frontal loop lacking late prominent rightward forces may be entirely normal

Certain vectorcardiographic changes may occur in emphysema even in the absence of significant right ventricular hypertrophy These changes result from the over inflation of the lungs and the more vertical position of the heart resulting from descent of the diaphragms

The electrical QRS forces tend to become oriented along the Y axis and a prominently inferior or superior axis may be observed In addition the interposition of overexpanded lung tissue between the heart and the chest electrodes may result in a marked attenuation of the anterior QRS forces producing a picture reminiscent of anterior infarction and sometimes making that diagnosis difficult to exclude Thus in a vectorcardiogram presenting with decreased amplitude and duration of anterior forces coupled with an abnormally superior or inferior frontal axis a diagnosis of emphysema could logically be supported in the presence of appropriate clinical information while in the absence of such data an incorrect diagnosis of anterior infarction could easily be made The reader is reminded of the basic assumptions of vectorcardiography referred to in the introduction In emphysema and in chest deformities such as kyphoscoliosis these basic assumptions—only approximations at best—break down and a qualitative descriptive approach to the QRS loops may be preferable to more quantitative analysis

The T loop in right ventricular hypertrophy is most commonly oriented to the left and usually exhibits clockwise rotation In the Type A loops the T loop is usually posterior and sometimes markedly so In the Type C loop the T loop orientation may be somewhat more leftward but the clockwise rotation is usually maintained Unfortunately for differential diagnosis by vectorcardiogram the T loops in right bundle branch block are identical to those of right ventricular hypertrophy This problem will be discussed in the section on T loops

The atrial vectorcardiogram is often of value when the QRS loops suggest right ventricular hypertrophy A P loop characteristic of left atrial overload in the presence of right ventricular enlargement by VCG always suggests mitral valve disease In contrast right atrial overload in the presence of right ventricular hypertrophy calls attention to a purely right sided problem P loops will be discussed in a separate section of this review

Biventricular hypertrophy (references 2 to 16 75 to 84)

Inasmuch as left ventricular hypertrophy adds left or posterior forces or both while right ventricular hypertrophy adds anterior or rightward forces or both it follows that in some instances such additions may be mutually cancellable and the resulting QRS loop may be entirely normal In most instances however vectorcardiographic clues may suggest the presence of biventricular hypertrophy although no really firm diagnostic criteria have been established which have stood the test of time

When the vectorcardiogram is characteristic of left ventricular hypertrophy because of high leftward voltage the presence of prominent large right posterior forces exceeding 20% of the total horizontal loop area should raise the question of the presence of right ventricular hypertrophy as well[7]

In a horizontal loop quite characteristic of left ventricular hypertrophy very large anterior forces exceeding 0 6 millivolts should call for additional explanation As usual with such loops the differential diagnosis for the prominent ante

Many perplexing problems in vectocardiography such as right bundle branch block with very prominent anterior forces or superior divisional block with prominent anterior forces are much better approached if the possibility of anterior conduction delay is kept in mind This will often allow the vectorcardiographer to avoid the pitfalls of mistaken diagnoses of associated dorsal infarction or right ventricular hypertrophy especially when the clinical picture indicates that neither diagnosis is likely

In the following sections on conduction disorders and on myocardial infarction frequent reference will be made to the problem of prominent anterior QRS forces and the content of the present section will be assumed as standard information

Myocardial infarction and pseudo infarction (references 2 to 16 102 to 160)

An extensive literature on the QRS loop abnormalities resulting from myocardial infarction is available in the textbooks atlases and symposia listed as general references in the first section of this review

Useful tabulations of quantitative criteria as well as excellent diagrams of the QRS loop abnormalities in infarctions of various location may be found in the texts by Chou and associates by Cooksey and colleagues and by Witham as well as in papers by Gunnar and co workers[10] by Van Herpen and associates[19] and by Eddleman and Pipberger[1] The classic findings in infarctions of significant size are easy to recognize and little dispute exists about diagnostic criteria The fundamental effect of an infarction is the subtraction of QRS potentials from the infarcted area resulting in a QRS shift in a direction away from the area of QRS potential loss

This subtraction effect which is maximal in the first half of the QRS loop but may spare the initial 01 or 02 sec segment in some cases results in an unexpected bowing or convexity of the loop away from the infarcted zone

For example in inferior myocardial infarction the first half of the QRS loop is characteristically displaced superiorly and to the left with an upward convexity away from the diaphragmatic location of the infarction This results in a clockwise rotation of a rather transversely placed frontal loop—a marked contrast to the usual counterclockwise rotation in that electrical position[1] If the initial 01 or 02 sec of the QRS loop are spared by the infarction and remain directed inferiorly the upward bowing effect between 20 and 40 or 50 msec is still quite evident and the diagnosis is apparent in the VCG

Thus the diagnosis of inferior infarction from the frontal plane vectorcardiogram can be easily established, even in the presence of R waves in Leads 3 and aV_F of the conventional scalar electrocardiogram[110, 111] The most useful quantitative criteria are a superior position of the 30 msec vector and an X intercept of the QRS loop located 0 3 millivolts or greater from the E point[11]

Very similar considerations govern the genesis of the abnormal horizontal loops in anterior myocardial infarction

Here as a result of anterior necrosis with a corresponding subtraction effect on the QRS loop the initial forces are directed posteriorly in marked contrast to the normal right and anterior position

In anteroseptal infarctions the 01 and 02 sec vectors are posterior while in more strictly anterior infarction the 01 or 02 sec vectors may remain anterior and right with subsequent posterior shift after 02 sec Some early clockwise rotation is common These loops which exhibit deformity after completion of the initial forces, thus are similar qualitatively to the inferior infarction loops in which the deformity develops after 02 sec[13]

In many anterior infarctions the normal counterclockwise rotation of the bulk of the horizontal loop is preserved However in more extensive infarctions and especially in those with a lateral component the rotation of the loop changes to clockwise[138, 13]

With lateral wall infarction the major change occurs in the loops which include the X axis (horizontal and frontal) The initial forces are abnormally rightwards exceeding the normal 022 sec duration for rightward forces

In the case of the frontal plane these exaggerated rightward forces commonly exhibit counterclockwise rotation (whereas in the normal such vertical forces usually rotate clockwise)

In the horizontal plane the abnormal rightward forces may be directed anteriorly if the lateral infarction is associated with dorsal involvement or posteriorly if the association is with anterior infarction In all of these instances the changes in direction and rotation of the loops

tinguishable from very similar loops found in patients proven by invasive techniques to be free of coronary disease or right ventricular hypertrophy

Some authors devoted themselves to establishing criteria which would distinguish between right ventricular hypertrophy and pure posterior infarction but did not attempt to separate these pathological conditions from the normal variant which was frequently encountered and which produced an identical QRS abnormality[90]

Until the mid 1970s the anatomical and functional divisions of the left bundle branch were generally considered as hemi divisions with the left bundle presumably dividing into a superior anterior branch and an inferior posterior branch Rosenbaum and colleagues[4] introduced and popularized the concept of electrocardiographic hemiblock as well as the concept that the entire intraventricular conducting system formed a *trifascicular* system when the right bundle branch was included along with the two subdivisions of the left bundle branch

The term hemiblock unfortunately implies that no room is left for other divisions or fascicles However the anatomic work of Demoulin and Kulbertus[5] and others has established that the anatomic *structure of the left bundle branch* instead of two equal divisions is extremely variable and most often includes a third anterior or septal fascicle Although great variation was encountered in the anatomic dissections of left bundle branch systems performed by Demoulen and Kulbertus[9] it was apparent that this anterior fascicle was sometimes a direct extension of the left main bundle sometimes a branch of the superior fascicle and sometimes a branch of the inferior fascicle

Thus an anatomic basis was laid for the concept that *anterior conduction delay might be the cause for some of the puzzling instances of* prominent anterior QRS loops in the demonstrated absence of right ventricular hypertrophy or of coronary disease with true posterior infarction [90]

Convincing evidence that this is indeed the case has come from two directions The first has been the production of prominent anterior QRS forces with atrial stimulation with the aberration disappearing at slower heart rates In these experiments which have been reported by three separate groups of investigators (Kulbertus and associates Cohen and colleagues[95] and Reiffel and Bigger[k]) other types of abberration such as right bundle branch block superior divisional block etc were also produced at different coupling intervals Although Reiffel and Bigger entitled their paper Pure anterior conduction delay A variant fascicular defect they do not attribute the delay to a disorder of conduction in any specific new fascicular subdivision but Kulbertus and colleagues believe that impaired conduction in the septal fascicle is indeed the cause for the observed abberration and anterior shift of the QRS

Hoffman and co workers[101] have described prominent anterior QRS loops in patients whose only coronary pathology was in the anterior descending artery In two such cases following unsuccessful coronary artery bypass surgery anterior myocardial infarction developed with a complete loss of the pre existing prominent anterior forces In the cases reported no coronary disease of vessels supplying the posterior wall or ventricular contraction defect of the posterior wall was observed[1]

It thus seems more than reasonable that at least in some cases prominent anterior forces may result from a conduction disorder probably *in the anterior or septal fascicle of the left bundle* branch as well as from right ventricular hypertrophy or from true dorsal myocardial infarction This concept is important because prominent anterior forces may be encountered combined with bundle branch block fascicular block myocardial infarction or ventricular hypertrophy It becomes necessary therefore to consider anterior conduction delay as the possible mechanism for prominent anterior forces whenever it is encountered—not only when it occurs in the pure form which originally led to the overdiagnosis of true posterior myocardial infarction *The concept of anterior conduction delay is supported by additional* logical force Since it is well known and accepted that conduction delay may shift the QRS to the right (right bundle branch block) to the left and posterior (left bundle branch block) superiorly (superior divisional block) or inferiorly (inferior divisional block) it would seem unreasonable that shift in an anterior direction could not occur just as easily especially as strong anatomic evidence for anterior fascicles has been presented

cardiomyopathies pulmonary emphysema and both left and right ventricular hypertrophies These causes of pseudo infarction in the vector cardiogram will be discussed separately

is dramatic and obvious and with a little practice, expertise can be achieved by any cardiologist familiar with standard electrocardiographic diagnosis and with the normal appearance of QRS loops as described previously.

These rather standard vectorcardiographic abnormalities have been correlated with clinical diagnoses of myocardial infarction (based on ECG criteria and enzymatic measurements) with coronary arteriography and ultimately with contrast ventriculography as well.[1, 10, 113, 179] In general rather good correlations have been observed between the classic loop abnormalities described above and with appropriately located coronary artery obstructions and areas of ventricular asynergy and akinesia.[133, 134, 13] In a study of 102 consecutive patients whose right anterior oblique left ventriculograms showed severe asynergy in the anterior and apical segments, 84 presented with horizontal QRS loops characteristic of anterior infarction but with clockwise rotation in the horizontal plane.[1] In another study patients with inferior myocardial infarction presenting with unexpectedly low ejection fractions were found by vectorcardiography to present additional evidence for anterior infarction not apparent in the standard 12 lead scalar ECG.

Thus it seems possible that some correlation of the vectorcardiogram with infarct size and with residual myocardial function can be made although it appears likely that such correlation will be crude at best. In experimental infarction with serial vectorcardiograms available direct approximations of infarct weight have been possible although this is seldom a situation which pertains clinically.

Much more difficulty is present in the analysis of the distal half of QRS loops especially the importance of small distortions called bites. Normally the QRS loops are inscribed smoothly and without sudden changes in rotation. The earliest workers in vectorcardiography correlated distal bites with autopsy evidence of myocardial scarring[1] and a theoretical basis for the phenomenon was developed by Selvester and colleagues[1] who constructed a computer model for the normal vectorcardiogram and were able to show that subtraction of small segments (as little as one % of the total) would result in bites similar to those observed clinically. Distal abnormalities have been correlated with infarctions in the diaphragmatic surface.

The clinical vectorcardiographer fortunately will usually encounter such bites when the proximal portion of the QRS loops exhibits classic deformities characteristic of infarction as described above. The real difficulty lies when such bites are detected in the absence of more proximal abnormalities. Witham has suggested that before significance is attached to such deviations they be identified in at least two planes, have a minimum duration of six msec and a minimal deviation of 0.1 millivolts.

Such bites are almost never found in normal young subjects but in contrast are fairly common in patients with angina, hyperlipidemia, diabetes and hypertension. Witham's text includes a valuable tabulation of distal QRS loop abnormalities resulting from infarctions in all areas.

Although the available literature indicates rather good correlations between the vectorcardiogram and clinical autopsy, arteriographic and ventriculographic evidence of myocardial infarction many difficulties nevertheless remain. The problem of large anterior loops which may result from true posterior infarction has already been discussed. However it should be pointed out that the diagnosis of true isolated posterior infarction is really quite unusual. Generally posterior infarction is associated with inferior or lateral infarction and the combination is easy to recognize.[1] The vectorcardiographer should be wary when the *only* abnormality found is an anterior QRS loop as the patient may be entirely free of coronary disease, his QRS loop representing anterior conduction delay as previously discussed.

Horizontal QRS loops with prominent anterior forces are easily recognized as they are displaced into the left anterior quadrant of the horizontal reference plane. Certain quantitative descriptors may be used to identify these loops. The anterior voltage measured on the Z axis reaches 0.5 millivolts or greater. The half area vector is ten degrees or more anterior to the X axis and maximum anterior forces are achieved at 30 msec or later. In addition the total duration of anterior QRS forces exceeds 42 msec. Unfortunately identical quantitative characteristics are found in patients with anterior conduction delay and dorsal infarction so that the differential diagnosis cannot be made on the basis of the vectorcardiographic characteristics.

Myocardial infarction may be mimicked by a variety of cardiac disorders, the most common are

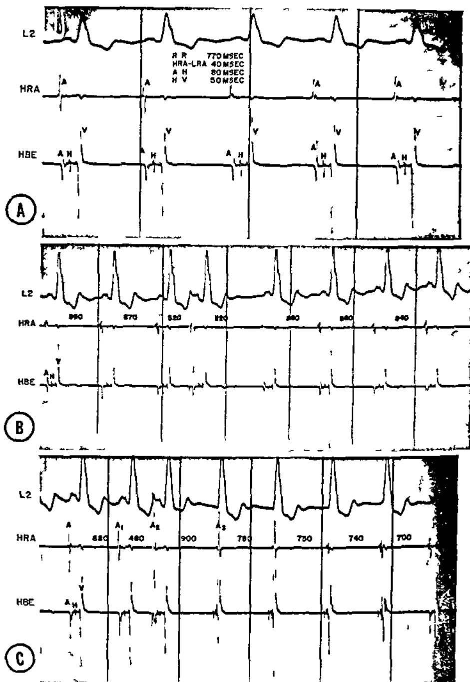

Fig 6 (Patient 5) The effect of atropine on the sinoatrial node From the top down Lead II high right atrial electrogram *(HRA)* His bundle electrogram *(HBE)* *A* the PR subintervals are normal except for an increase in the HRA LRA interval to 40 msec *B* an artificial premature beat is followed by a full compensatory pause *C* after administration of 1 0 mg of atropine the atrial premature beat is followed by a full compensatory pause which is terminated by an AV junctional rhythm at a slightly slower rate than the sinus rhythm The last beat is a fusion between the sinus and AV junctional beat

of the sinus node occurred simultaneously in this patient However it should be pointed out that there are also other explanations for the paradoxical effect of atropine on the automaticity of the sinus node as previously discussed[5]

b Atropine in the evaluation of ischemic heart disease Cokkinos and associates[42] showed that higher ventricular rates induced by atrial pacing after the administration of atropine led to an increase in ST segment depression and the incidence of angina pectoris in patients with angiographically proved CAD

The effect of atropine on cardiac arrhythmias and conduction Part 2

Paul Schweitzer MD FACC
Herbert Mark MD FACC
Bronx N Y

II Diagnostic use of atropine

a Sinus node dysfunction The nonspecific nature of the clinical symptoms caused by sinus node dysfunction and the low sensitivity of the electrophysiological findings indicate a need for additional tests to facilitate the diagnosis of sinus node dysfunction[35, 9, 81] Atropine may satisfy this need[35]

In patients with sinus bradycardia caused by sinus node dysfunction atropine in doses of 1 to 2 mg does not increase the sinus rate by more than 10 to 15 beats/minute and never over a rate of 90/minute[29, 3] *On the other hand when sinus* bradycardia is caused by extracardiac factors atropine exerts a marked positive chronotrophic effect This use of the drug in the diagnosis of sinus node dysfunction has been recently challenged by Dighton who was not able to confirm this difference in the response to atropine

Atropine produces sustained AV junctional rhythm in some patients with sinus node dysfunction Although this arrhythmia developed in a small number of patients with symptomatic sinus node dysfunction its occurrence will support the diagnosis of sinus node dysfunction Two unusual effects of atropine on sinus node recovery time may further aid in the diagnosis of this disorder Paradoxical prolongation of the sinus node recovery time[50, 51] and the replacement of sinus rhythm by AV junctional rhythm when atrial pacing is suddenly stopped also substantiate the diagnosis

The possibility of improved sinoatrial conduction and unmasking of abnormal sinus node automaticity after the administration of atropine is suggested in the following patient A 72 year old woman with a history of paroxysmal atrial fibrillation was hospitalized because of syncope The ECG showed sinus rhythm and LBBB The resting electrophysiological measurements were normal except for a high low right atrial interval which was prolonged to 40 msec (normal 25 msec) (Fig 6A) Atrial premature beats introduced before the administration of atropine did not reset the SA node regardless of the coupling interval (Fig 6B) This finding was consistent with a first degree SA block[4] Administration of atropine accelerated the heart rate from 69/minute to 88/minute During measurement of sinoatrial conduction time atrial premature beats introduced in late diastole (89% to 96% of the spontaneous sinus cycle) were followed by a full compensatory pause (Fig 6C) However the sinus node was suppressed and the return rhythm was AV junctional after atrial premature beats with a shorter coupling interval The AV junctional beats occurred following the expected full compensatory pause The mechanism underlying this effect of atropine is not clear but we believe that because atropine abolished the sinoatrial conduction disturbance the premature atrial impulses penetrated into the sinus node and suppressed it This mechanism is similar to the one which was used for the explanation of the paradoxical effect of atropine on the sinus node recovery time[50, 5] If our hypothesis is correct then an abnormal automaticity and conductivity

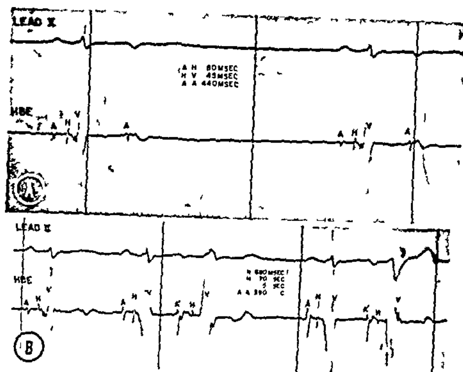

Fig 8 (Patient 7) The effect of atropine on atrial premature beats *A* Lead II and His bundle electrogram *(HBE)* show sinus beats *alternating with blocked* atrial premature beats *B* following administration of 0.5 mg of atropine the sinus rate accelerates and the conduction through the AV node improves permitting the conduction of *atrial premature beats* The *QRS* complexes of the atrial premature beats are wide because of aberrant conduction

only for patients in the coronary care unit but also *prior to* hospitalization for patients with acute myocardial *infarction* [27]

Subsequently experimental findings [7,8] and case reports [91] *challenged* the routine use of atropine in patients with acute myocardial infarction and asymptomatic bradycardia First it was shown that atropine itself *may increase* ventricular irritability [92] and that increased vagal tone is not *necessarily* harmful in experimental myocardial *infarction* [87,9] or in patients with myocardial infarction [93] At the same time Epstein and co workers pointed out that while atropine suppresses so called *benign* ventricular premature beats it is less *effective* in the therapy of malignant ventricular premature beats The effect of atropine on *hypotension* was also questioned Finally the possible *adverse effect* of increased heart rate on the *size of* myocardial infarction also came into *consideration* *In other words* uncontrolled tachycardia caused by *atropine* may increase the size of the infarct and this *led* to doubts *about the usefulness* of the drug

The possible adverse effect of atropine and the *experimental findings* noted above suggested a need for re evaluation or redefinition of the r of atropine in managing patients with acu myocardial infarction Despite a number of co trary recommendations we believe that the use atropine in acute myocardial infarction is st justified [95,96] and it remains the drug of choice patients in whom sinus node suppression is com plicated by hypotension or increased ventricul irritability The drug is not indicated however uncomplicated sinus bradycardia and shoul probably not be given without medical superv sion Because the adverse effects of atropine ar dose related [25] it is important that the dose of th drug be kept between 0 4 and 0 8 mg It has bee shown by Chadda and colleagues [26] that i patients with acute myocardial infarction dose of 0 8 mg or less are usually not associated wit increased ventricular irritability Unanswered however is the question whether patients who d not respond to lower doses of atropine should be treated by insertion of a temporary pacemaker o with increasing doses of atropine At this time we prefer to use a temporary pacemaker in these nonresponsive patients

The clinical effectiveness of atropine in

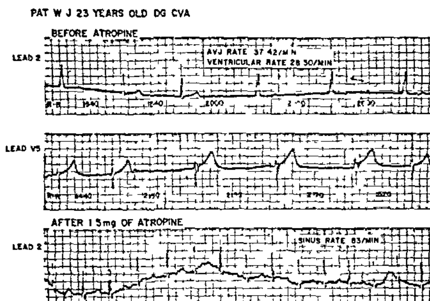

Fig 7 (Patient 6) The effect of atropine on the sinoatrial node Leads II and V recorded before the administration of atropine show a slightly irregular AV junctional rhythm with alternating idioventricular beats After the administration of atropine a sinus rhythm resumes

c Normalization of Wolff Parkinson White syndrome Since the original description of the Wolff Parkinson White (W P W) syndrome it has been known that atropine can restore a normal QRS complex in some patients with this syndrome This effect is unpredictable however[5, 8] Normalization of W P W syndrome after atropine occurs in subjects in whom the drug facilitates conduction through the AVN and decreases the ERP of the AVN Refractoriness and conduction through the AVN become shorter than through the accessory pathway and therefore activation of the ventricles occurs by way of the normal pathway This effect is of clinical significance mainly in patients with suspected myocardial infarction The ECG of W P W syndrome not only simulates myocardial infarction but also masks the presence of an acute myocardial infarction Normalization of the QRS complex therefore reveals information of diagnostic value in patients with suspected myocardial infarction and the W P W syndrome

III Therapeutic indications for atropine

a Sinus node dysfunction Administration of atropine is indicated in patients with sudden onset of sinus node suppression complicated by hypotension or increased ventricular irritability The indication for atropine is less certain in patients with chronic symptomatic sinus node dysfunction It is possible that atropine or other long acting parasympatholytic drugs may be of some benefit in patients in whom for any reason a permanent pacemaker is not implanted

The effects of atropine in a patient with marked suppression of the sinus node is seen in Fig 7 The patient was a 23 year old man admitted to the hospital in deep coma because of a ruptured subarachnoid aneurysm There was no SA node activity and the AV junctional rate was 37/minute to 42/minute (Fig 7) Intermittent suppression of the AV junctional pacemaker occurred causing an idioventricular rhythm Administration of 1 5 mg of atropine restored a regular sinus rhythm

b Myocardial infarction During the past few years attitudes about the use of atropine for its effect on the heart rate in patients with acute myocardial infarction have been revised several times Atropine was recommended in acute myocardial infarction and sinus bradycardia because slow heart rate was associated with hypotension and increased ventricular irritability[15] and the beneficial effects of atropine on hypotension and ventricular arrhythmias were confirmed in the majority of clinical studies[15] In addition atropine was also used prophylactically to accelerate the heart rate in patients with bradycardia but without hypotension and ventricular irritability Use of the drug for bradycardia was suggested not

adverse effects in acute myocardial infarction initiated a series of investigations in which the arrhythmogenic effects of atropine were intensively studied, especially as mediated through the parasympathetic nervous system. That the autonomic nervous system is in a state of imbalance early in the acute stage of myocardial infarction was stressed by Webb and co-workers.[98] While some studies demonstrated that vagal stimulation increases the ventricular fibrillation threshold in dogs with acute myocardial infarction,[99] other studies suggest that the effect of the vagus on the ventricular fibrillation threshold can only be demonstrated on the normal myocardium and not on the ischemic myocardium.[100] Kolman and co-workers[101] believe that the beneficial effect of the vagus nerve in stabilizing ventricular irritability depends on the level of adrenergic activity, with vagal effects becoming apparent only if there is concomitant increased activity of its sympathetic counterpart.

Reviewing the adverse effect of atropine in acute myocardial infarction, we found that the only factor which was important in the pathogenesis of ventricular arrhythmias in man was the acceleration of the heart rate after atropine. An increased heart rate almost always preceded the appearance of increased ventricular irritability. The localization of the infarct, the age of the patient, or the time of administration of atropine did not seem to play an important role in the pathogenesis of ventricular arrhythmias after atropine, although tachycardia was more likely to appear after higher doses of atropine. This relationship is shown in the next illustrative case.

A 72-year-old patient was seen one hour after the onset of severe chest pain. The blood pressure was 70/50 mm Hg and the ECG showed marked sinus bradycardia (25/minute to 34/minute), first degree AV block and an acute inferior myocardial infarction (Fig. 9A). Administration of 0.5 mg of atropine did not influence the sinus rate. Following a second 0.5 mg dose of atropine the sinus rate accelerated to 130/minute (Fig. 9B). The sinus tachycardia was associated with increased ST segment elevation and was followed by ventricular tachycardia and ventricular fibrillation (Fig. 8C and D). Defibrillation was successfully carried out and the patient made a good recovery (Fig. 9E). This case demonstrated that atropine-induced ventricular irritability is preceded by acceleration of the sinus rate and supports the observation that at least 1.0 mg of atropine is necessary for the adverse effect of the drug.

Summary

The effects of atropine on various components of the specialized conduction system of the heart and the myocardium itself are reviewed. These actions are sometimes unpredictable or paradoxical, depending on the component showing the dominant effect and the health of the entire system. Atropine is best known for its chronotropic effect. Improved sinoatrial conduction has been demonstrated but the effect on the refractoriness of atrial muscle is unsettled. Atropine stimulates the atrioventricular (A-V) junctional pacemaker and facilitates conduction through the A-V node. The response of the subjunctional portion of the specialized conduction system to the drug is unpredictable and controversial in some respects.

Atropine is useful in the diagnosis of sinus node dysfunction, in the evaluation of coronary artery disease during atrial pacing, and in attempting to produce normal conduction in patients with the Wolff-Parkinson-White Syndrome. Its principal therapeutic application is in correcting the hypotension-bradycardia syndrome occurring during acute myocardial infarction. It also has a role in the temporary management of sinus node dysfunction. Atropine may also cause arrhythmias including atrial fibrillation, A-V dissociation, ventricular tachycardia, and ventricular fibrillation. The clinical settings in which atropine may be arrhythmogenic are discussed.

patients with myocardial infarction complicated by AV conduction disturbances is less certain Atropine may improve second and third degree AV block in patients with either inferior or anterior myocardial infarction [24, 96] but this effect on AV conduction is unpredictable We also believe that because of the variability of the response to atropine and the possible adverse effects of the drug a temporary pacemaker is the therapy of choice if the AV block causes hemodynamic deterioration or ventricular arrhythmias

IV Adverse effects of atropine

Until recently the adverse effects of atropine on the cardiac rhythm were thought to be infrequent and of little clinical significance Because atropine is now used more frequently than it was in the past we have become more aware of the implications of atropine induced complications In addition the drug is often administered to patients with acute myocardial infarction and unstable cardiac rhythm which is probably another cause of the higher incidence of adverse effects of atropine Most of the undesired effects of atropine are self limited and except for serious ventricular arrhythmias do not themselves require therapy The use of smaller doses of atropine in patients with acute myocardial infarction is probably the best way to avoid these complications

The adverse effects of atropine on the heart were extensively reviewed through 1970 by Scherf and Schott [97] Atrial fibrillation induced by vagolytic drugs was reported by Onnius in patients with acute myocardial infarction Supraventricular tachycardia after atropine was discussed earlier [65]

The occurrence of ventricular premature beats or ventricular tachycardia after administration of atropine in patients without cardiac disease is rare Dauchot and Gravenstein [99] who studied the effect of atropine on the cardiac rhythm in 79 patients showed that the drug caused ventricular premature beats in one older patient On the other hand simultaneous administration of atropine with halothane and cyclopropane which are myocardial depressants may lead to serious ventricular arrhythmias even in patients without heart disease

The following case shows a possible pseudo adverse effect of atropine A His bundle recording from a 68 year old woman with a history of

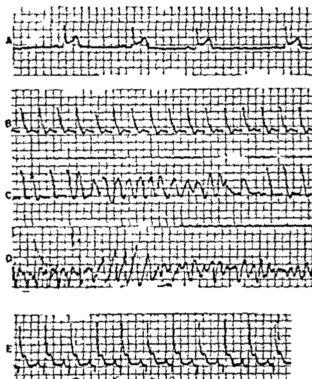

Fig 9 (Patient 8) Atropine-induced ventricular fibrillation in a patient with acute inferior myocardial infarction *A* lead II shows sinus bradycardia (25-34/min.) PR interval of 0.2 second and ST segment elevation *B* following the administration of 1 0 mg of atropine the sinus rate accelerates to 130/min This is associated with an increase in the ST segment elevation. *C D* ventricular tachycardia and ventricular fibrillation then appear *E* sinus rhythm is restored by defibrillation.

syncope is shown in Fig 8 The ECG revealed sinus rhythm frequent atrial premature beats some blocked and others with aberrant ventricular conduction His bundle recording confirmed the blocked atrial premature beats which were the cause of the bradycardia (Fig 8*A*) Administration of 0 5 mg of atropine did not abolish the atrial premature beats but improved the AV conduction so that all the atrial premature beats were now aberrantly conducted (Fig 8*B*) Blocked atrial premature beats are readily recognized on 12 lead ECG s because the atrial deflection can be identified at least in some of the leads However if only a single monitor lead is analyzed as is usually done in the CCU the identification and diagnosis of nonconducted APC s may be difficult Had this patient been monitored with a single lead the appearance of APC s after atropine might have been erroneously interpreted as an adverse effect of the drug

The wide use of atropine and its potential

Of right ventricular congestive heart failure

Selected pathophysiologic aspects of left ventricular congestive heart failure were discussed previously but right ventricular congestive heart failure (RVCHF) was not considered in detail in these discussions The same general arguments that apply to the left ventricle (LV) the left pump of the heart also apply to the right ventricle (RV) the right pump of the heart However there are specific differences For example there are essentially 500 c c of blood in the pulmonary blood vessels and 4,500 c c in the systemic blood vessels when the heart is normal and fully compensated and each ventricle is pumping the same volume of blood and the two pumps are well synchronized For illustrative purposes if it is assumed that each ventricle pumps 100 c c per stroke and the heart rate is 100 beats per minute and if all things remained equal the volume of blood in the pulmonary and systemic circulations would remain stabilized as indicated i e 500 and 4,500 c c respectively for the pulmonary and systemic vascular systems. However if the right ventricle were to fail slightly and pump 99 c c of blood per stroke while the left ventricle continued to pump 100 c c per stroke each minute 100 c c of blood would be removed from the pulmonary circulation and pumped into the systemic circulation. The pulmonary circulation would become relatively empty or dry " and the volume of blood in the systemic circulation would increase—a volume increase which the systemic veins could readily accommodate provided they are not "tightened by sympathetic nervous system activity But regardless of how small the total pulmonary blood volume becomes the volume of blood within the pulmonary vessels is always equal to the volume of the lumina of the pulmonary vessels thus the pulmonary vessels, especially the pulmonary veins would become relatively loose as the hoop tension of the wall reduced unless the tone of the smooth muscles in the walls of the vessels actively increased by means of autonomic nervous system activity If all of the blood from the lungs (500 c c) was displaced into the systemic circulation, the systemic circulation could readily accommodate the 500 c c just as it so readily accommodates a 500 c c blood transfusion

But as is well known clinically with right ventricular congestive heart failure (RVCHF) the neck veins become distended and the patient develops systemic venous hypertension edema ascites pericardial and pleural effusion etc Why do these pathophysiologic manifestations occur? The abnormal non-synchronized state of the two pumps (RV and LV) results in the clinical state of RVCHF with the increase in tone (constriction) of the systemic veins as described previously Why and by what mechanism this increase in α and β-adrenergic sympathetic tone of the systemic blood vessels occurs are not known [illegible] clinical and physiologic data indicate that this increase in sympathetic tone or activity does occur The mechanisms by which water and electrolytes are subsequently retained are also not known. The water and electrolyte retaining pathologic mechanisms must be related in large part to alteration in renal function (not renal disease), as noted before resulting from dysfunction of the two cardiac pumps The increase in sympathetic tone could initiate physiologic phenomena which could produce the well known renal dysfunction of CHF responsible for the accumulation of edema fluid.

Surely in less than 5 minutes the left ventricular stroke volume would have to decrease to the stroke volume of the RV but the volume of blood in the pulmonary circulation could remain reduced It could slowly return to normal levels by means of readjustments in the stroke volume of the two ventricles and readjustments of the vascular renal, autonomic nervous system dysfunction, etc But if the original factor which caused the RV to reduce its stroke volume in the first place were still present one can only wonder if the sympathetic (α and β) tone would return to normal even if the volume of blood in the pulmonary vessels returned to the normal level of 500 c c

This discussion of CHF illustrates again what great difference in the state of circulation could be produced by only 1 c.c. stroke volume difference between the two cardiac pumps. One can readily calculate the rates of change in the circulation that could be produced by any reasonable differences in stroke volume for the two pumps and at different heart rates.

Furthermore is there such a *clinical* state as RVCHF with a normal LV function i.e RVCHF without LVCHF? Theoretically it could exist with "pure or strict pulmonary stenosis, such as with a congenital defect or in cor pulmonale

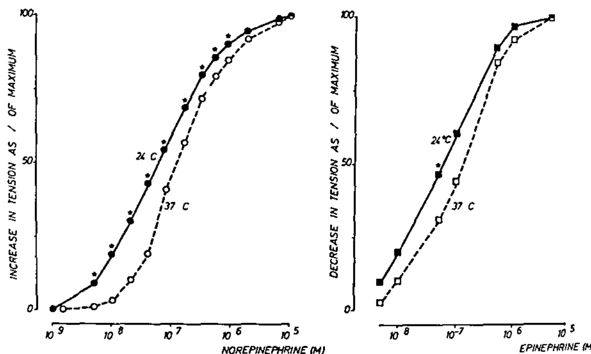

Fig 2 Demonstration that in cutaneous vessels moderate cooling augments the responsiveness of the vascular smooth muscle cells to both the alpha and beta adrenergic effects of catecholamines The experiments were performed on isolated rings of canine saphenous veins *Left* the rings were made to contract with increasing concentrations of norepinephrine throughout the experiment neuronal disposition of norepinephrine as well as beta adrenergic receptors are blocked by the appropriate pharmacological agents Cooling from 37 (o--o) to 24 C (●—●) shifts the dose response curve to norepinephrine to the left the maximal contractile answers to the catecholamine were not significantly different at both temperatures (Data from Ref 9) Potentiation by local cooling is also obtained during sympathetic nerve stimulation *Right* the rings were first made to contract with acetylcholine in the presence of phentolamine to block alpha adrenergic receptors the relaxation caused by increasing concentrations of epinephrine was then investigated at 37° (□ -□) and 24 C (■—■) Cooling markedly facilitates the inhibitory effect of epinephrine Similar augmentation by moderate cooling of the beta adrenergic responsiveness has been described for isoproterenol and norepinephrine * = value at 24 C significantly different from that at 37 C ($P < 0.05$ Student s t test)

ents the arterial and venous responses to sympathetic nerve ctivation The enhanced arteriolar constriction limits the mount of blood flowing through the skin The augmented enoconstriction directs the venous return to the deep venae omitantes which run alongside the deep arteries Unlike itaneous vessels deep vessels dilate when they are exposed to ie colder blood coming from the skin This favors the counter-current exchange of heat which warms up the enous blood returning to the body core The augmented esponse of cutaneous blood vessels to sympathetic nerve ctivity during moderate cooling is due to two factors (Fig 1) irst lowering the temperature delays the disappearance of ie adrenergic neurotransmitter from the junctional cleft etween the adrenergi nerve endings and the cutaneous ascular smooth muscle because it inhibits neuronal uptake nzymatic degradation and diffu ion of norepinephrine hus, the amount of transmitter in the icinity of the alpha drenergic receptors of the va ular effector cells increases urther moderate cooling greatly augments the respon ive ess of the cutaneous vascular m ooth muscle to norepineph ine (Fig 2 *left*) because the affinity of their alpha adrenergic receptors significantly increases this increase in affinity holds not only for norepinephrine but also for alpha adrenergic antagonists At the same time moderate cooling augments the sensitivity of the vascular smooth muscle for the beta adrenergic effects of catecholamines which in normal conditions presumably tempers the increased responsiveness to the alpha adrenergic effect of these substances (Fig 2, *right*)

It is tempting to assume that in primary Raynaud s disease the vasospasm associated with exposure to cold involves the local potentiating effect that temperature has on the cutaneous vasomotor response to sympathetic nerve activation, and in many instances is only an exacerbation of the physiological mechanism The importance of the autonomic nervous system in providing the initiating signal for vasoconstriction is illustrated by the observations that the onset of the symptoms is frequently related to situations where emotional stress augments the sympathetic outflow to the cutaneous vessels, and that reserpine or sympathectomy may alleviate the symptoms ' However the abnormality is primarily a dysfunction of the vascular smooth muscle cells, since epi

Thermosensitivity of cutaneous vessels and Raynaud's disease*

Raynaud s disease is characterized by prolonged pasm of the digital arteries of the hand when they are exposed to a cold stimulus particularly when the subjects are emotionally upset The exact mechanism underlying the vasospasm is unknown

Thermoregulatory needs are the main determinants of cutaneous blood flow Hence the sympathetic outflow to the cutaneous arterioles arteriovenous anastomoses and veins is continuously adjusted by the hypothalamic thermoregulatory centers. When the body temperature increases the sympathetic outflow to the skin blood vessels decreases and the weat glands are activated and produce kinins as a result the arterioles, the arteriovenous anastomoses, and the veins open Large amounts of blood are shunted to the latter which act as a capacious radiator for the physical exchange of heat When the body temperature decreases, the sympathetic outflow to the skin is augmented, sweat secretion is inhibited and the dissipation of heat is restricted Besides thermoregulatory adaptations, the skin vessels participate in homeostatic reflexes and in the cardiovascular response to emotional stress

Local cooling (from 37 C to about 15 C) greatly aug

*Presented at the meeting of the Belgian Angiological Society on January 13, 1979

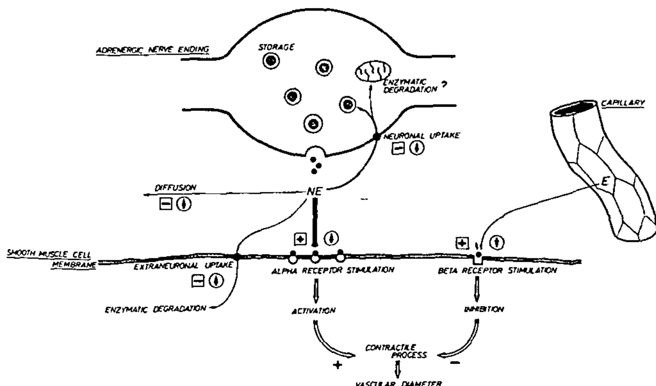

Fig 1 When the sympathetic nerves are active cooling affects both the adrenergic nerve ending and the vascular smooth muscle cell in cutaneous vessels The release of norepinephrine from the adrenergic nerve ending is most likely not affected by moderate cooling Neuronal uptake and enzymatic degradation of norepinephrine are depressed by moderate cooling as well as by diffusion of the neurotransmitter out of the junctional cleft This partially explains the increased constriction upon cooling in densely innervated cutaneous vessels since the concentration of the adrenergic neurotransmitter increases in the vicinity of the effector cells. In addition more norepinephrine binds to the alpha adrenergic receptor sites at lower temperatures leading to greater activation of the contractile process and thus to increased constriction of these vessels. The potentiating effect of cold is partly offset by the facilitation of the beta adrenergic effects of the catecholamines NE = norepinephrine E = epinephrine □ = effect of temperature O = contractile response ↑ = augmentation ↓ = depression

disturbances in blood flow may be responsible for clinical manifestations in BMLS and the condition has been called an ischemic cardiomyopathy at the Montreal Heart Institute [2] on account of an unduly large LV mass in relation to coronary blood flow

These abnormal findings have not always been confirmed when other investigators have applied the same tests to their groups of MLP patients [2] However it is very difficult in this situation where the index entity is common and the clinical spectrum wide to be sure that studies with disparate results have compared like with like Measurement of LV function in the intact human heart is problematical and the frequent coexistence of mitral regurgitation and LV wall motion abnormalities in patients with MLP coming to catheter study [4] adds to the methodological difficulties A drawback of thallium imaging of myocardial perfusion is its rather poor resolution a particularly unfortunate feature when the supposed abnormalities must lie in the small arteries beyond the resolution of standard contrast cineangiography Moreover myocardial uptake of thallium is not purely flow-dependent and if as Selwyn and associates have stated regional disturbances in myocardial perfusion can be identified with this indicator only when metabolic abnormalities affecting cellular uptake are present it follows that those MLP patients with stress scintigraphy defects have disturbed myocardial cellular metabolism Thus it is prudent to consider the extant reports of myocardial dysfunction and perfusion abnormalities in BMLS with realistic caution

Opportunities for direct examination of myocardial tissue obtained at necropsy from subjects with BMLS are not common and no distinctive abnormality has been recognized [2] Only recently have techniques of biopsy during cardiac catheterization made it possible to obtain endomyocardial tissue samples safely during life and it is of great interest that the two studies so far published have both presented evidence of myocardial abnormality in BMLS The report from Stanford done in 1978 is of right ventricular biopsy by a technique refined in cardiac transplantation follow up studies and carried out in 14 patients with BMLS Light microscopy revealed an increase in endocardial and interstitial fibrosis in eight cases Electron microscopy in 11 cases showed mitochondrial degenerative changes usually marked or severe in all and definite myocyte degeneration in four Nuclear chromatin clumping and intracell edema were more prominent in BMLS biopsies than in control specimens obtained at transplantation from 10 normal donor hearts The inevitable criticism of this important study is that the tissue from the right side of the interventricular septum may not be representative of the myocardium beneath the prolapsing mitral valve

Left ventricular tissue is accessible for percutaneous transarterial biopsy and a method by which a bioptome can speedily and repeatedly be passed via a Teflon long sheath to obtain multiple endomyocardial biopsies has been described in detail With experience in developing this technique and an established laboratory dedicated to the analysis of biopsy specimens obtained during open heart surgery we were able at St Thomas Hospital London to address in a direct and novel fashion the question of ar normality of the LV in BMLS patients undergoing cardiac catheterization Endomyocardial LV biopsies from 11 patients wi h 1LP distressing chest pain little or no mitral regurgitati and normal coronary arteries were examined by cellular chemical and biophysical methods [1] Comparison was made with biopsies from a good LV" control group in which normal LV function was judged by seven or eight indices and from a bad LV' control group in which these indices were markedly abnormal Histochemical findings in the MLP biopsies ranged from normal to very abnormal and on a semiquantitative rating of over all histochemical abnormality the MLP group were significantly worse ($p < 0\,001$) than the good LV controls and also worse than the bad LV controls but not significantly so The results for monoamine oxidase (MAO) activity reflecting ability of myofibrils to metabolize catecholamines were particularly poor with eight of the 11 MLP specimens showing abnormal MAO activity compared with 11 of 21 in the bad LV and only two of eight in the good LV group The ability of muscle fibers in unfixed biopsy sections to respond to the standardized stimulus of adenosine triphosphate (ATP) plus ionic calcium was measured in terms of alteration in birefringence of the myofibrils believed to be brought about by ATP mediated orientation of myosin micelles [a] The birefringence response to ATP was markedly impaired in tissue from MLP patients with the group results in a position between the good LV and bad LV controls and significantly different from both The clear distinction ($p < 0\,005$) between the good LV controls and the MLP group suggests a distinct abnormality of muscle function in the latter for this birefringence method has been shown capable of registering myocardial deterioration during cardiopulmonary bypass. Such evidence of abnormal muscle function in this subgroup of patients with MLP and chest pain is of particular importance because it has been obtained by a method independent of the problems of assessing myocardial function in the intact ventricle

The myocardial biopsy evidence from Stanford and London [7] strongly supports the concept of a diffuse abnormality of the myocardium in those patients with BMLS in whom symptoms have been sufficiently prominent to warrant cardiac catheterization It is difficult to refute use of the term cardiomyopathy in this situation Because of the major role of catecholamines in myocardial contraction the MAO abnormalities could well be part of the fundamental defect responsible for impairment of the birefringence response to ATP in the specimens from MLP patients The beta adrenergic blocking drug propranolol has acquired a reputation for usefulness in treating chest pain and other symptoms in BMLS and there may be some link between the histochemically demonstrable MAO abnormalities and this clinical impression No theory to explain the chest pain of BMLS has yet gained general acceptance [2] but the cellular abnormalities to which the biopsy data now testify surely point to a metabolic/ biochemical mechanism as the most likely explanation. Further investigation of the pathophysiology and treatment of BMLS are now indicated and will be particularly welcomed by those in clinical practice who struggle with the management of patients with severe non anginal chest pain and without any demonstrable cardiac abnormality except MLP

sodes of vasospasm still can be induced by exposure of the fingers to cold after sympathectomy In patients where the phenomenon is primarily due to hypersensitivity of the alpha adrenoceptors to the sensitizing action of cooling, ther apeutical effects are obtained with alpha adrenergic blocking agents it is to be expected from the studies on isolated blood vessels that the vessels exposed to the cold will be particular ly susceptible to alpha adrenergic blockade and thus that doses of blocking agents may be used which have little effect on general hemodynamics. Raynaud s disease sometimes is uccessfully treated with beta receptor stimulating agents. Treatment with beta adrenergic blocking agents induces Ray naud s phenomenon Raynaud s disease is relatively fre quent in patients suffering from hypothyroidism In the animal, beta adrenergic sensitivity decreases with a e a process which can be reversed by administration of thyroid hormone These different observations all imply that Ray naud s disease could be due to a relative lack of beta adrenergic sensitivity of the cutaneous vessels This then would exaggerate the augmentation by local cooling of the vasoconstri tor response of these vessels to the alpha adrener gic effect of the catecholamines

Myocardial mysteries surrounding mitral leaflet prolapse

Excessive bulging of one or both leaflets of the mitral valve has proved to be a remarkably common disorder but the hearts of subjects with such valves have not readily yielded up their secrets. Certain symptoms notably chest pain and palpitation mysteriously associated with mitral leaflet prolapse (MLP) have prompted investigation of the state of the left ventricle (LV) as well as the mitral valve itself in the symptomatic primary form of the disorder designated billowing mitral leaflet syndrome (BMLS) by Barlow and Pocock in their recent Editorial in this JOURNAL

Suggestive evidence of a myocardial abnormality in patients with MLP has been obtained by a variety of means Crude indications of LV dysfunction in terms of elevated resting LV end-diastolic pressure (LVEDP) an abnormal rise in LVEDP and/or cardiac index on exercise or a failure to lower LVEDP appropriately in response to atrial pacing, have been reported Abnormal myocardial lactate metabolism has been documented in four studies Reports from Toronto and Milwaukee of ²⁰¹ thallium myocardial perfusion imaging defects on stress testing have fostered speculation that local

N S = refers to non-significant p value greater than 0 05

cell production increases relatively linearly with decreases in hemoglobin oxygen saturation

However in patients with lung disease where arterial carbon dioxide tension may be abnormal leading to respiratory acidosis or alkalosis there is a less well defined relationship between the degree of hemoglobin unsaturation and the red cell mass than is characteristically seen in normal subjects at altitude It has been suggested that patients with chronic lung disease have an attenuated bone marrow response or that red cells have a decreased life span which could contribute to the variable red cell mass in lung patients compared to normals at altitude Another factor which could result in a lower red cell mass for a given degree of arterial unsaturation is the increased cardiac output seen in some patients with chronic lung disease With a higher cardiac output the delivery of oxygen to various tissues is increased and if intrarenal oxygen sensors responsible for the erythropoietin response were exposed to a normal oxygen supply then it is understandable why some patients would not have secondary polycythemia in spite of decreased arterial blood oxygen saturation

Although increased red cell mass improves the oxygen carrying capacity of blood it also increases blood viscosity which tends to impede blood flow Since blood with its particulate matter is not a Newtonian fluid its viscosity increases with increases in red cell concentration The shape of individual red cells also affects viscosity and shape changes leading to elevated viscosity occur in hypoxic and hypercapnic blood Because of differing metabolic rates in individual tissues blood viscosity could be quite different in individual vascular beds. Also viscosity is affected by vascular geometry and by the rate of blood flow Controlled changes in hematocrit and blood viscosity have been shown to affect the resistance to flow in the pulmonary[a] and peripheral circulations The clinical significance of increased viscosity on pulmonary vascular resistance is controversial since both improvement in and no significant change in pulmonary vascular resistance have been reported following a reduction in hematocrit by venesection

The clinical management of secondary polycythemia is not generally agreed upon Although symptomatic improvement in mental acuity vitality and breathing ability has been volunteered by patients whose polycythemia was treated by venesection objective data on the mechanisms producing these symptomatic changes are s[illegible]se Venesection does not alter measured pulmonary function although work capac ity has been demonstrated to improve

The most direct way of reducing red cell mass is by venesection It reduces both the red cell mass and the blood volume in cardiac failure due to cor pulmonale and it has been advocated as a preventive measure a ainst the recur rence of cardiac failure after compensation A consensus of opinion has arisen that venesection is of doubtful value expect to reduce the incidence of thrombotic complications noted when the red cell mass is increased

We measured cerebral blood flow with xenon 133 before and after venesection in six chronic hypoxic pulmonary diseas patients with polycythemia We demonstrated that venesec tion increased cerebral flow and that the increase appeared to be preferentially greater to the cerebral cortex (Table I) We did not correct the cerebral blood flow values in Table I fo changes in partition coefficient resulting from changes i hemoglobin concentration because there is uncertainty abou the actual tissue blood xenon 133 partition coefficient in th living brain It is known that this coefficient increases wit decreases in hemoglobin concentration and use of the correc tion factor would result in our measured prevenesectio cerebral blood flow values being lower than those shown Therefore venesection to correct secondary polycythemia ma actually result in a larger increase in cerebral blood flow tha that reported in Table I

The improved flow to the cerebrum could explain th symptomatic improvement noted by these patients sinc neither mechanical lung function blood gas values or pulmo nary artery pressure (as judged from the distribution o pulmonary blood flow) changed significantly in them

Venesection has been shown to increase cerebral blood flo in patients suffering from primary polycythemia with o without cerebrovascular accidents Cerebral blood flow ha also been demonstrated to increase in association with th general improvement noted on recovery from ruptured cer bral aneurysms It would appear that optimal blood flo occurs at a physiological hematocrit of 45%

A less direct approach to achieve a lower hematocrit and t reduce pulmonary artery pressure is by adminis ration o continuous oxygen which has been found to be clinicall beneficial in patients with polycythemia secondary to hypo emia There is a reduction in hematocrit in about 6 weeks an a decreased incidence of hospitalization due to cor pulmon ale[20] In patients with severe hypoxemia this therapeut

Management of secondary polycythemia with hypoxic lung disease*

Although hypoxemia resulting from chronic lung disease is a common medical condition it is relatively uncommon to see polycythemia associated with these lung disorders The polycythemia secondary to hypoxemia is mediated by increased erythropoietin production but erythropoietin levels and therefore red cell mass can also be increased in the presence of certain tumors and renal disorders.

The increase in red cell mass is a beneficial physiological adjustment to hypoxemia since more oxygen can be carried in each milliliter of blood for a given arterial oxygen tension Because of the shape of the oxygen dissociation curve there is not a dramatic decrease in the oxygen saturation of hemoglobin and therefore oxygen content of blood until oxygen tension falls below about 65 mm Hg It is interesting that red

Toxic polyneuritis and toxic hepatitis related to long term perhexiline maleate therapy

To the Editor

In the article Assessment of perhexiline maleate in angiographically proven intractable angina by M Afzal Mir (AM HEART J 96 350 1978) some side effects of the drug are reported such as tremor dizziness nausea though not severe enough to impair the general condition of the patient However in a few cases serious side effects have been observed indicating liver and nervous system damage with anatomical toxic hepatitis segmentary demyelination of the peripheral nerves and decreasing of proprioceptive reflexes pallesthetic deficit and visual impairment

We have recently observed extremely severe liver and peripheral nerve impairment in a 51 year old male patient who had been taking perhexiline maleate (PM) at the following dosages 600 mg daily for 1 month 400 mg daily for the next 3 months and 200 mg daily for a further 16 months

Symptoms of peripheral neuropathy appeared during the last 3 months of treatment namely peripheral tingling of the four limbs weakness of the four limb muscles (mainly of the legs) impairment of the flexion and extension movements of the feet of the flexion and abduction movements of the thigh and impairment of the fine movements of the fingers with muscular hypotrophy Furthermore he was complaining of headache dizziness waddling gait with pallesthetic deficit visual impairment and bilateral papilledema The physical examination demonstrated a large and hard liver with an edge 4 cm below the costal margin (not previously observed) and physical findings of peripheral neuropathy The SGOT was 100 I U SGPT was 60 I U and alkaline phosphatase 5 I U

On electromyogram (EMG) examination a slight reduction of motor unit recruitment on voluntary contraction was observed in the extensor muscles of the forearms and in the small muscles of the hands In the lower limbs a moderate motor unit reduction was observed distally more evident in the muscles of the anterior compartment of the legs Motor conduction studies performed in ulnar median deep peroneal and posterior tibial nerves showed a severe slowing with a marked time scattering of the motor responses These findings were in agreement with a peripheral neuropathy in which segmental demyelination was likely to be the main feature The conduction velocity of peripheral sensorial and motor nerves showed the values in Table I

The ECG showed inferior fibrosis and ST T abnormalities but the typical perhexiline maleate changes were absent

The clinical picture was interpreted as a severe peripheral neuropathy associated with toxic h patitis probably drug induced Four months after discontinuing the treatment with PM the papilledema was markedly reduced the gait was almost completely normal there was a mild improvement of the lower limb proprioceptive refle s and a mild muscular atrophy was still present

Table I

	Actual velocity	*Normal velocity (range)*
Median nerve	29 2 M /sec	57 71 M /sec.
Ulnar nerve	31 7 M /sec	53 7 73 M./se
Sciatic internal popliteal nerve	29 8 M /sec	40 55 M /sec
Sciatic external popliteal nerve	13 8 M /sec	4? 57 M /sec.

Two months later the EMG showed a dramatic impro ment of the neural conduction speed liver enlargeme however was still present and hepatic enzymes were s elevated (SGOT 56 I U SGPT 28 I U) several months af discontinuing the drug The severe neurological lesions may due to the presence of an undiagnosed liver disease primary secondary to perhexiline maleate leading to a storage of I in the liver and in the neural tissue The former hypothe seems to be more likely since in a group of five patients w normal liver function who had been taking PM in simi large doses conduction abnormalities of the peripheral ner have not been observed

We can conclude that liver function must be assessed befo long term PM therapy is begun while clinical signs of hepa and peripheral nerve involvement should be carefully look for during treatment

regimen may be inadequate to reduce the hematocrit to a physiological range because arterial oxygen saturation may remain decreased in spite of increasing the inspired oxygen concentration

This study of cerebral blood flow and polycythemia indicates that venesection to a physiological hematocrit may be beneficial for patients with secondary polycythemia because of apparent improvement in central nervous system function mediated by improved cerebral perfusion Venesection should perhaps be repeated until the hematocrit reaches an optimal level of 45% Continuing examination of the effect of rheological alteration on regional flow to all body organs should be pursued

entazocine No patient had received antiarrhythmic drugs Ve do not think that data from this latter group had a oticeable value in the context of our report and for this ason we had omitted relating them

We are aware that verapamil can reveal a latent sick sinus ndrome or induce hypotension because of this (as previous stated in our Letter) we avoided using the drug in patients ith sinus bradycardia or systolic blood pressure lower than 00 mm Hg Although these seem to be logical precautions we ave never observed undesirable side effects

With regard to the possibility that the disappearance of entricular premature beats (VPBs) had taken place sponta eously instead of being a drug effect we think that unlikely nce rapid disappearance of VPBs occurred in 85% of the atients also the lack of relapses for at least three hours after rug injection can hardly be considered fortuitous When PBs are treated with a bolus of lidocaine in most cases it is ecessary to prolong the infusion of the drug thus suggesting hat VPBs of acute myocardial infarction are not always ransitory Moreover many reports prove that the effect of erapamil given as a bolus intravenously is not attenuated ompletely in 10 minutes but show that the pharmacological ffects of the drug last longer—thus suggesting a longer alf life and/or a preferential myocardial uptake and binding f verapamil

Finally we would like to make some comments about Dr hmad s statement that verapamil has no value in the control f ventricular arrhythmias We too for a long time were onvinced of this and have considered (and still do) verapamil he drug of choice in the treatment and prophylaxis of paroxysmal supraventricular tachycardia However the ncreasing experimental evidence that arrhythmias following acute myocardial infarction can be related to the slow response action potentials led us to verify the usefulness of a drug (such as verapamil) which inhibits slow responses in treatment of VPBs of acute myocardial infarction Our results are positive and support the hypothesis that in man VBPs of acute ischemia are also related to the slow inward current.

The distinction of ventricular arrhythmias on the basis of the activating current seems to us to be a very important advancement in arrhythmology

To the Editor:

In our series there were no serious side effects, mainly because it was a short term study and none of the patients took perhexiline maleate for more than six weeks. Serious neurological complications have been observed among those who have taken perhexiline on a long term basis, as happened in the case reported here by Dr Carruzzo and colleagues. These workers suggest that neuropathy may be due to liver disease in patients taking perhexiline. In our series serum transaminases were raised in about 30% of patients and other workers have reported abnormal liver function tests in 10% to 17% of patients, whereas the incidence of neuropathy is about 0.1% in patients taking perhexiline. Subclinical neuropathy indicated by abnormal electrophysiological measurements, occurs in two thirds of patients—a substantially higher proportion of patients than those who develop clinically recognizable neuropathy. It is obvious that abnormal electrophysiological tests and abnormal liver function tests do not help in finding the patients at risk for developing the neurological syndrome. The only way one can guard against such serious complications is by seeing the patients every month or six weeks, by examining them for serious loss of weight, questioning closely for early symptoms of neuropathy (i.e., numbness, tingling etc.) and by repeating liver function tests. Most workers would agree that the drug should be stopped if a patient continues to lose weight, develops early signs of neuropathy, or if liver function tests deteriorate or remain persistently abnormal.

An early withdrawal of perhexiline is important since most of the complications caused by this drug are reversible.

Verapamil therapy

To the Editor:

A recent Letter to the Editor by Fazzini and associates warrants further comments. They state that 28 patients with myocardial infarction who presented with frequent ventricular premature beats (VPBs) in the first 48 hours of their illness were treated with intravenous verapamil. They failed to mention these patients' ages, any concomitant therapy, or any other associated disease.

Rosing and colleagues have recently reported a 77-year-old woman who developed sinus arrest and hypotension following one 80 mg oral verapamil capsule. It is noteworthy to stress that this patient had manifested no findings that would have been suggestive of sick sinus syndrome.

Verapamil, given as a bolus intravenously, has a very short half life and its effect is attenuated completely within 10 minutes. It is therefore not clear whether the disappearance of VPBs up to three hours after verapamil was due to the effect of this drug or occurred spontaneously.

Systemic hypotension and prolongation of PR interval are the commonest side effects of verapamil[3]. I strongly believe that this drug has no place in the management of VPBs of acute myocardial infarction. Furthermore, verapamil appears to be of no value in the control of ventricular arrhythmia. Verapamil depresses the sinus discharge rate; therefore it is contraindicated in patients with sinoatrial disease, which usually may be found in the older population. Of course verapamil is the drug of choice in the treatment and prophylaxis of paroxysmal supraventricular tachycardia.[4]

Finally, I should emphasize that verapamil should not be used within 48 hours after administering beta adrenergic blockers, disopyramide or quinidine therapy. Physicians caring for patients with cardiac arrhythmia should bear in mind the possible drug interactions and side effects of verapamil and be more selective in choosing patients for treatment with this agent. Nevertheless, the introduction of verapamil will constitute a very significant advance in cardiovascular therapeutics in this country.

Reply

To the Editor:

We wish to thank Dr. Ahmad for his observations.

The age of our patients ranged between 40 and 65 years; the mean age was 58 years. Systemic hypertension was present in nine patients and diabetes mellitus was present in four. Fifteen patients had received nitrates and 20 had received

Announcements

Eighth Annual Cardiac Symposium

The Department of Medicine and Cardiac Rehabilitation of Georgia Baptist Medical Center will present its Eighth Annual Cardiac Symposium in Atlanta on October 10 1980 The guest lecturer will be William Kannel, M D Co-directors of the symposium are Gerald F Fletcher M D., and John D Cantwell, M.D For further information contact Gerald F Fletcher M.D., Director of Internal Medicine, 300 Boulevard N E., Atlanta, Ga. 30312

Joint Conference on Stroke and Cerebral Circulation

The Stroke Council of the American Heart Association, in association with the Cerebrovascular Surgery Section of the American Association of Neurological Surgeons, The Canadian Stroke Society of the Canadian Heart Foundation and The Society for Vascular Surgery will present a Sixth International Joint Conference on Stroke and Cerebral Circulation at the Century Plaza Hotel in Los Angeles on February 12 through 14 1981 The conference is an open meeting, whose purpose is to provide a common forum for the presentation of material relating to all aspects of cerebrovascular disease and the physiology and pathology of the cerebral circulation Abstracts dealing with the clinical or experimental aspects of the pathogenesis, diagnosis, medical and surgical management of vascular disease of the brain and spinal cord are welcome Deadline for the receipt of abstracts is August 29 1980 (postmarked) Accepted abstracts will be published in the January 1981 issue of the journal *Stroke* of the American Heart Association.

Guidelines and further information may be obtained from Administrator Postgraduate Programs, American Heart Association, 7320 Greenville Ave., Dallas, Texas 75231 Telephone (214) 750-5441

Cardiac Imaging and Cardiovascular Radiology

A course entitled "Cardiac imaging and review of cardiovascular radiology for residents and fellows," will be presented April 1 through 4 1981 at the Islandia Hyatt House in San Diego California, by the Faculty of the Department of Radiology of the University of California, San Diego Medical Center Program Director is Michael J Kelley M D For further information, contact Mary J Ryal Radiology P O Box 2305 La Jolla, Calif 920?? Telephone (714) 459 9787

Lucien Dautrebande Pathophysiology Prize for 1979

The Professeur Lucien Dautrebande prize for 1979 in the amount of $37 000 has been awarded to Professor J E Desmedt Director of the Brain Research Unit Faculty of Medicine of the University of Brussels, Brussels, Belgium. Dr Desmedt has been chosen by an international jury for his original contributions to neuromuscular diseases, to the mechanisms of voluntary motor control in man, and to brain mechanisms studied by the evoked potentials method in relation to maturation aging neurological disorders, and cognitive performance After receiving the Dautrebande prize from the hands of H.M Queen Fabiola of the Belgians, Dr Desmedt emphasized in his acceptance speech the increasing importance of the systems approach of pathophysiology and of the development of physiological methods applied to intact man.

The next competition for the Dautreband Prize will be held in 1982 and the award will be approximately $46 000 All particulars may be secured by writing to Dr Stalport, President 35 chausee de Liége 5200 Huy Belgium. For consideration in the 1982 competition, all papers must be received *before* December 15 1981.

Society of Nuclear Medicine Meeting

The Eighteenth Annual Meeting of the Society of Nuclear Medicine will be held in September 1980 in Erlangen/Nurnberg W Germany The main theme of the meeting is "Nuclear Medicine with its Interdependencies," with special reference to cardiology and hepatogastroenterology For further information, contact Prof Dr F Wolf, 18th International Annual Meeting Society of Nuclear Medicine, Institut und Poliklinik fur Nuklearmedizin der Universitat Erlangen Nurnberg Krankenhausstrasse 12 D-8500 Erlangen W Germany Telephone 09131/853411 153416

Book reviews

Ambulatory ECG Monitoring Edited by Shlomo Stern M D F.A.C.C., London and Chicago 1978 Year Book Medical Publishers, 197 pages.

This small book edited by Stern and with several contributors reviews the technic and problems associated with applications of ambulatory monitoring The book is clinically oriented The 14 chapters review very well many problems related to Holter monitoring The use of the monitor in the evaluation of arrhythmias effects of therapeutic agents and the results of cardiac management are clearly discussed The book describes thoroughly and very well the application of Holter monitoring The illustrations are good and the book should be available to all cardiologists and other physicians who use ambulatory monitoring This is a good book but it does not represent a critical discussion of the limitations applications, and abuses concerned with Holter monitoring

Progress in Cardiology Vol 7 Edited by Paul N Yu M D and John F Goodwin M.D., Philadelphia 1978 Lea & Febiger 228 Pages. Price $17 00

This is the seventh volume of the *Progress of Cardiology* The subjects discussed vary widely in the field of cardiology They include discussions of embryology the role of the nervous systems in cardiovascular control emotions catecholamines and the electrocardiogram diet drugs and pulmonary hypertension and angina pectoris new operations for congenital cardiac anomalies and recent advances in peripheral vascular disease The eight chapters are written for the clinician and housestaff in training in internal medicine and cardiology This is another good volume and the subjects discussed are not only interesting but important

Dynamic Cardiac Auscultation and Phonocardiography By Abner J Delmar M.D F.A.C.P., F.A.C.C and Emanuel Stein M.D., M.P.H., F.A.C.P., F.A.C.C F.C.C.P Philadelphia 1979 W B Saunders Company 1023 pages. Price $55 00

This is an atlas of over one thousand pages of excellent illustrations of simultaneous recordings of heart sounds apex cardiograms phases of respiration and a reference ECG Carotid pulse tracings are included in most of the illustrations The associated text is clearly written and the legends are quite helpful Readers will find this to be an excellent review of phonocardiography Page 181 contains an interesting illustration of mid systolic click" which does not occur in mid systole but rather in late systole This illustration for example clearly indicates the looseness of nomenclature and definition of findings The Whoop or Honk is nicely illustrated on page 183 The book is very good The illustrations are excellent This book should be of value to all cardiologists internists and trainees in internal medicine and cardiology Careful and thoughtful study of this book should improve every clinician s cardiac auscultation

Advances in Cardiology: New Approaches in the Diagnosis and Management of Cardiovascular Disease Edited by John H K Vogel Basel, 1979 S Karger AG., 139 pages Price $53.50

This issue of *Advances in Cardiology* is concerned with both diagnosis and treatment The many contributors review effectively noninvasive techniques use of positron-emitting radionuclides use of propranolol and newer antihypertensive drugs pharmacologic treatment of patent ductus arteriosus diet exercise medical and surgical management of unstable angina surgical treatment of congenital heart disease and other important cardiovascular problems. The respective short reviews were presented at the Ninth Cardiovascular Conference held at Snowmass The presentations are interesting and should prove of considerable value to cardiologists as well as to non-cardiologists The subjects discussed are timely such as the results of medical and surgical management of unstable angina

Coronary Artery Disease Recognition and Management. By Charles E Rackley M D and Richard O Russell Jr M D., New York 1979 Futura Publishing Company 439 pages Price $33 00

This book edited by Rackley and Russell with 14 additional contributors, reviews very well the contemporary approach to the diagnosis and management of coronary artery disease The 15 chapters include discussions of the natural history of coronary artery disease precordial movement echocardiography radionuclide studies exercise testing clinical syndromes of coronary artery disease coronary arteriography cardiac catheterization use of nitrates myocardial metabolism bypass surgery diagnosis and management of acute myocardial infarction. The illustrations are good and a useful bibliography is provided This is a good review of many important aspects of the diagnosis and management of coronary artery disease It is rather interesting that the role of electrocardiography is neglected in the considerations, whereas the newer more complex procedures are given prominent exposure This book should be of interest to readers who are interested in learning the role of these newer procedures in cardiology Readers will find this a useful book especially housestaff and trainees in cardiology

etc) cardiovascular symptoms (exertional chest pain dyspnea and leg pain) socio personal characteristics (educational level consumption of alcohol coffee etc), metabolic and miscellaneous features (cholesterol uric acid leukocyte count forced vital capacity etc)

The results obtained were essentially consistent for all race sex groups Smokers who later quit (ex smokers) showed statistically significant differences from smokers who continued the habit in a number of cardiovascular symptoms socio personal characteristics and metabolic and miscellaneous traits In the 288 comparisons made with persistent smokers the ex smokers at index examination were statistically different in 130 or 45% at the $p < 05$ level, and the majority of these (84) were significant at the $p < 01$ level Controlling for smoking quantity had little effect on the observed differences between the persistent quitters and persistent smokers Furthermore at index examination (when still smoking) the ex smokers characteristics were not very dissimilar from those of nonsmokers Thus the investigation clearly indicated that ex smokers are not a representative sample of smokers with regard to their CHD related characteristics or the extent of the smoking habit And, most importantly the nature of the differences revealed that smokers destined to quit (ex smokers) showed characteristics at baseline indicative of *lower CHD risk* than smokers destined to continue

The findings of our study prompt the following conclusions The observational studies referred to above which show lower CHD rates for ex smokers than for continuing smokers are flawed having failed to observe the basic principles of valid scientific inference Their comparisons of the CHD outcomes of the two groups are *biased* since they have made the false assumption that ex smokers are representative of continuing smokers except for the change in the smoking habit With ex smokers self selected to begin with and at lower CHD risk at baseline it is small wonder that their CHD outcomes in these widely publicized studies are found to be lower than those of continuing smokers The extent to which the CHD outcomes are lower than those of continuing smokers resulting from baseline differences remains to be determined

The results of our new study have received strong support from Rose and Hamilton in their recently published report on a randomized controlled trial of smoking cessation in middle aged English male civil servants at high risk of cardiorespiratory disease After almost eight years of follow up they found no significant differences in mortality rate between the intervention group and the normal care group despite the greater cigarette smoking cessation (58% at 3 years) in the intervention series than in the normal care group (14% at 3 years) The authors state the interpretation of these observational studies [3] is not straightforward for men who stop smoking are not a representative sample of smokers comparison of the two groups is biased the reversibility of the risk of cigarettes to the smoker s life may have been overestimated in observational studies Disappointingly we find no evidence at all of any reduction in total mortality

What are we then to believe about the effect of stopping smoking on the risk of CHD? Despite the conventional view that cessation of smoking reduces the risk of mortality from heart disease there is now evidence that the comparisons of the CHD outcomes between ex smokers and smokers in the observational studies are biased and *unreliable* Our new study reported above indicates that ex smokers at baseline are at lower CHD risk to begin with thus contributing to their eventual lower CHD outcomes In addition the results of the first randomized controlled trial of the possible effect of smoking cessation in middle-aged men have shown no improvement in their rate of mortality relative to those who were not urged to stop smoking thus the reversibility of the claimed risk of cigarettes to the smoker s life has not been demonstrated Accordingly it is reasonable to believe there is no proof that stopping reduces the risk of heart disease

Surgeon General s Report—1979

The second event bearing on the question of smoking and CHD is the publication of the Surgeon General s 1979 Report on Smoking and Health The 1979 Report summarizes its views on smoking and cardiovascular diseases as follows In summary for the purposes of preventive medicine it can be concluded that smoking is causally related to coronary heart disease for both men and women in the United States Unfortunately the text of the report fails to validate the conclusion

The main thrust of the 1979 Report is with the

American Heart Journal

September 1980 Volume 100 Number 3

Editorial

Smoking and coronary heart disease what are we to believe?

Carl C Seltzer Ph D
Cambridge Mass

Two recent events have raised serious questions as to what we are to believe about the conventional view that cigarette smoking is a cause of coronary heart disease (CHD)

Interpretation of ex smoker data

The first event relates to the interpretation of ex smoker data indicating that CHD mortality rates of persons who stopped smoking are substantially lower than those of persons who continued smoking The interpretation given to these data is that smoking cessation directly results in the reduction of risk of heart disease mortality The most commonly cited investigations in support of this line of thinking are the observational studies of Doll and Hill s British doctors Hammond s American men and women Kahn s U S veterans and the Framingham Study Underlying this alleged CHD benefit however is the assumption that ex smokers are a representative sample of smokers except in so far as they have stopped smoking But the proof of the validity of this assumption has not been forthcoming This is a crucial point in the comparison of the CHD outcomes in the two smoking groups For if the assumption of representativeness is invalid and significant baseline differences are observed between ex smokers and smokers for relevant factors then the possibility exists that the mortality comparison of ex smokers and continuing smokers is biased

For the first time in a very large series of subjects according to race and sex we observed the proper baseline for the determination of whether or not ex smokers were a representative sample of smokers This baseline involved the study of the CHD related characteristics of ex smokers *before they stopped smoking* and their comparison with those of persistent smokers The results of this study are briefly reviewed below

Using the longitudinal records from the Kaiser Permanente multiphasic health check ups the study compared 25 CHD related characteristics of ex smokers *before they stopped smoking* with those of persistent smokers and nonsmokers A total of more than 25 000 subjects white men and women black men and women with three or more consecutive health check ups formed the basis of the analysis For the criteria of the classification of the subjects the designated index examination and the list of CHD related characteristics the reader is referred to the publication [5] The minimum of three or more examinations was used in order to insure a rigorous classification of the smoking categories Thus ex smokers (persistent quitters) were subjects who had at least one examination at which they reported both a current and past history of cigarette smoking followed by at least two examinations in which they reported complete cessation of smoking The CHD related characteristics fell into arbitrary categories cardiovascular manifestations (blood pressure hypertension

Thus after many years of search and experimentation the mechanisms by which smoking (cigarette smoke) might enhance various manifestations of CHD have not been satisfactorily established Many hypotheses have been advanced as explanations of possible pathways between smoking and enhancement of CHD but these remain postulations To arrive at a conclusion that smoking is causally related to CHD proven mechanisms are the essential links between the evidence of statistical association of smokers with excess CHD in a number of countries These proven mechanisms have not been forthcoming

There are a number of other aspects of smoking and CHD in the 1979 Report which are not supportive of the causal hypothesis For example angina pectoris an important manifestation of CHD is not deemed to be at risk from smoking In this connection the 1979 Report states the predictive risk factor association of smoking with the incidence of angina pectoris is not clear and epidemiological data on the association between cigarette smoking and angina pectoris and cerebrovascular disease manifested as stroke are not conclusive

In discussing the effect of smoking on blood lipids the 1979 Report finds that The data are not very uniform As for cholesterol its association with smoking is minimized stating that There may indeed be a minor tendency for cigarette smokers to have slightly elevated blood cholesterol levels for whatever reasons And in discussing cholesterol levels in the Framingham Study it is concluded that These differences were too small to account for the observed difference in risk associated with type of smoking habit Also with regard to the Tromso and Framingham studies the 1979 Report asserts that almost identi[illegible]al HDL cholesterol levels among smokers and non[illegible]mokers were found there was no significant [illegible]sociation between them

The 1979 Report al[illegible]l[illegible]es the effect of smoking on the [illegible] tem in proper context It [illegible]ates The [illegible]nd transient effect of smoking [illegible] man is [illegible] heart rate and blood pressure t[illegible] The relationship between [illegible]rt[illegible]ion is made crystal clear in [illegible]tations Available data indicat[illegible] not a major risk factor for hypertension and in practice the association is slightly negative — Cigarette smoking does not induce chronic hypertension — There is no apparent relationship between smoking and incidence of hypertension

The 1979 Report is also notable for what it does not mention or fails to give adequate attention to No mention is made that there is an absence of excess CHD risk in the elderly (ages 65 and over) in the continuation of cigarette smoking[1] No mention is made that the evidence of an association between CHD and duration of cigarette smoking is not clear owing to the absence of such an association in the Framingham Study th[illegible] Albany Heart Study Dorn s U S veterans study and the Canadian veterans study[11] No mention is made of the importance of other variables known to be important in CHD (in their confounding effects) such as educational level income class marital status occupation job advancement and ethnicity[1] The 1979 Report concludes that cigarette smoking is causally related in United States women but fails to mention that the Framingham Study (the U S Public Health Service s own study) found essentially no relation between cigarette smoking and heart disease in women[18] The constitutional hypothesis is dogmatically dismissed principally on the basis that "risk of smokers reverts to normal or nonsmokers level after they cease to smoke necessitating a change in ex smokers in their constitutional factor in midlife Such a view shows a disturbing lack of understanding of the constitutional hypothesis and is contrary to the evidence that ex smoker CHD rates are related to their basic characteristics rather than to a flat out ascription to smoking cessation The evidence of a constitutional genetic factor from the data of twin studies is stated to be inconclusive despite the consistent results of Cederlof and colleagues[7], Friberg and associates[1] Lundman[9] Liljefors and De Faire[1] No mention is made of Burch s contention that the secular trends in sex specific and age specific death rates from CHD in England and Wales (1921 1973) strongly support the constitutional hypothesis[23]

Apart from the matter of association perhaps the most common argument raised in behalf of the causal hypothesis is that stopping smoking reduces the risk of CHD This has been considered by the American Heart Association s 1977 Ad Hoc

statistical association of cigarette smoking and CHD The association showing smokers relative to nonsmokers having more specific manifestations of CHD in the form of myocardial infarction and sudden death is evident So is the association of smokers with necropsy manifestations of atherosclerosis These conditions have strong appeal to epidemiologists and others to draw causal conclusions as to the effect of smoking on CHD despite the universal dictum stated by the 1979 Report that ' correlation is not synonymous with causation Beyond the matter of statistical association of smokers with myocardial infarction sudden death and atherosclerosis (from necropsy) the *necessary evidence of a causal connection is not* clear nor determined The cold reality is that the mechanisms by which smoking (tobacco smoke) allegedly enhances CHD have not been established As far back as 1964 the Surgeon General s Advisory Committee on Smoking and Health found no unique cardiovascular effects were demonstrated to seem likely to account for the observed associations of cigarette smoking [smokers] with an increased incidence of coronary disease Since then however many hypothetical mechanisms have been advanced starting with the Surgeon General s 1967 Report[1] successively to the latest 1979 Report Facile postulations have been the order of the day with nicotine and carbon monoxide featuring among the guilty culprits

At times the 1979 Report is quite candid as to what is known concerning the mechanisms by which cigarette smoke affects various aspects of CHD With regard to atherogenesis the 1979 Report states At the present time animal experiments on atherogenesis and CO have provided conflicting data and must be regarded as unsatisfactory Further The *mechanisms* by which smoking enhances atherogenesis require elucidation And still further specific morphological features of plaques that would be characteristic of smoking have not been delineated And again The *overall impression from available data is* that nicotine does not affect atherogenesis in animals The summary on this subject seems very weak First it remarks there is no reasonable doubt that cigarette smoking enhances *atherogenesis* while *further on in the* same summary section it confesses that Relatively little is known about the mechanisms by which smoking enhances atherogenesis or increases the risk of heart attack The 1979 Report is singularly maladroit in summarizing this area of concern

In connection with myocardial infarction the 1979 Report states The mechanism of effect is usually attributed to an enhancement of coronary atherosclerosis in smokers and the consequent occurrence of cardiac ischemia and ischemic necrosis of heart muscle Myocardial infarction then is attributed to the smoking enhancement of atherosclerosis which at present is based on speculation or doctrinal statements rather than on rigorously interpreted evidence Note the following quotations it can be *hypothesized* (my *italics*) *that patients on the* border of myocardial ischemia may be pushed into impending or actual infarction by the effects of nicotine and CO and it may be *speculated* (my italics) that in the presence of coronary atherosclerosis of a degree insufficient to cause ischemia the action of smoking on platelet pathophysiology may precipitate occlusive thrombosis and infarction No wonder the 1979 Report finds A major need is to understand better the mechanisms by which smoking can induce or affect the evolution of myocardial infarction

As for the mechanisms by which smoking may precipitate sudden cardiac death the 1979 Report states The mechanisms *postulated* (my italics) to explain the association of sudden cardiac death with smoking have been described under atherogenesis and under myocardial infarction as *possible* (my italics) mechanisms for effects of smoke nicotine and CO It is of collateral interest that the 1979 Report finds that The act of cigarette smoking does not appear to be immediately related in time to sudden death The section on sudden death is concluded with the following The mechanisms by which smoking might induce sudden death in addition to an exacerbation of coronary artery arteriosclerosis can be *hypothesized* (my italics) from experiments that indicate that an exacerbation of regional ischemia *may promote electrical instability of the heart* fibrillation or asystole Further research will be required if these mechanisms are to be well understood and if they are to be shown to be actual mechanisms in man in relation to smoking *and sudden death* Medicine will agree with the 1979 Report when it states The mechanisms of sudden death its precursor states and preventive therapy require further elucidation

Committee on Cigarette Smoking and Cardiovascular Diseases as the final link in the chain of evidence incriminating cigarette smoking as a causal factor in cardiovascular disease The 1979 Report asserts that Cessation of cigarette smoking reduces over time the increased risk attributable to smoking toward the risk of nonsmokers That these views are untenable is now apparent from the new evidence we presented in the first part of this article

Conclusions

What then remains in the 1979 Report on CHD with which we can readily agree? We can agree with the 1979 Report that coronary atherosclerosis is of primary importance in the development of CHD through myocardial ischemia We can agree that the available necropsy data indicate that cigarette smokers tend to have more severe and extensive atherosclerosis of the coronary arteries than nonsmokers But this does not mean *ipso facto* that cigarette smoking enhances atherosclerosis for the mechanism(s) by which smoking might enhance atherogenesis or increase the risk of heart attack have not been established There have been no consistent clinical or experimental data in animals or man that clearly support the leap from association to enhancement

We can also agree that there is a statistical association between cigarette smoking and CHD in the United States While it is true as well with regard to some western European countries no significant statistical associations between smoking and CHD have been reported in Finland the Netherlands Italy Greece Yugoslavia Japan and Puerto Rico[14] No convincing evidence has been forthcoming to account for the absence of associations in so many countries some of which are not too far removed in their nutritional and metabolic circumstances from the U S This explains the stricture in the summary statement in the 1979 Report limiting the conclusion to men and women in the United States

Accordingly the statistical associations of cigarette smokers with atherogenesis myocardial infarction and sudden death in a limited geographical sense are what remains from the assertion that smoking is causally related to CHD Since as the 1979 Report points out mere association is not synonymous with causation this is insufficient for valid scientific inference without attendant support from clinical and experimental data This attendant support is lacking since the necessary mechanisms indicating how cigarette smoking might possibly enhance CHD are either unknown or not established and owing to the absence of proof that stopping smoking reduces CHD

The associations however still remain to be explained In the case of ex smokers we found that self selection appeared to be responsible for the differences in CHD outcomes between ex smokers and continuing smokers That self selection may also be the basis of the CHD differences between smokers and nonsmokers has not been ruled out The crucial study of baseline characteristics of smokers and nonsmokers remains to be performed by epidemiologists The constitutional hypothesis must be examined closely and without prejudice for possible explanations

For the present then it is reasonable to believe that stopping smoking does not reduce the risk of CHD and that there is no established proof that cigarette smoking is causally related to coronary heart disease

Rome, Italy

Athlete's ECGs represent a major problem for many cardiologists and sports physicians, as in some cases the tracings significantly differ from those of normal untrained persons and sometimes closely resemble pathological ECG patterns like ventricular hypertrophy[1-4] and ST-T wave ischemic changes.[5-7] These findings have been attributed to the anatomical and physiological cardiac adaptations to heavy prolonged training, mainly of the endurance type. Particularly, sinus bradycardia, bradyarrhythmias, and first degree A-V block have been attributed to the absolute or relative increase of resting vagal tone following training, and therefore these have been regarded as "physiological" phenomena.

Wenckebach second degree A-V block is a very uncommon finding in normal people, but is significantly more frequent in young athletes, physically active middle aged persons, and is surprisingly frequent in horses.

Notwithstanding, these epidemiological data have not solved the central question if a vagogenic mechanism by itself can be entirely responsible for these anomalies. The nightly occurrence of second degree A-V block of Wenckebach type in clinically normal students seems to support the opinion that purely functional A-V conduction disturbances may occur. On the other hand, this reassuring view has been recently questioned by Young and associates, as they observed in seven out of 16 adolescents and young adults the progressive worsening of A-V conduction up to fixed complete heart block.

In order to ascertain the organic or functional nature of conduction disturbances in athletes, invasive electrophysiological investigations could be performed. However, as the large majority of athletes who undergo cardiological examination are clinically asymptomatic and fit, we believe it ethically correct to attempt only a noninvasive evaluation of conduction abnormalities in these athletes and to refer to invasive electrophysiological studies only those athletes with abnormal responses.

Since 1977 we began to submit all athletes with major A-V conduction disturbances to a noninvasive protocol study consisting of reflex autonomic tests, autonomic drug administration, and physical exercise. The present paper reports the results of such a diagnostic approach performed in a group of 10 top ranking athletes with Wenckebach type (Mobitz I) second-degree A-V block.

Material and methods

Ten males, 15 to 27 years old, were referred to us by the Physicians of Sports Medicine Institute of Rome because of the spontaneous or induced occurrence of Wenckebach second-degree A-V block on the ECG during a routine medical evaluation for sports aptitude. They practiced different sports, mostly of an endurance type (Table I). Wenckebach second degree A-V block

diograph at a paper speed of 25 mm /sec Subsequently all subjects were submitted to the following maneuvers

1 Eyeball pressure (EP) right (RCSP) and left carotid sinus pressure (LCSP)

2 Graded Valsalva maneuver (Valsalva) using a sphygmomanometer bl wn up to 40 mm Hg for as long as possible

3 Rapid open hyperventilation (ROHV) for at least 30 second

4 Rapid st ding ...

ECG recordi w ... onds before was continued th ... done for 10 seconds after e ...

Basal tracings were analyzed for (1) type of rhythm and sinus rate in beats/minute (b/min) by averaging 5 P P intervals and (2) A V conduction pattern

The effects of reflex tests on S A and A V nodes were evaluated (1) by measuring the maximum and minimum sinus rate achieved during and after each test and by checking for the possible occurrence of a shifting of the atrial pacemaker sinus arrest, or S A block (2) by observing if any change in A V conduction occurred

Pharmacological tests First a bolus of isoproterenol 5 mcg × 70 kg /body weight (BW) was administered intravenously under continuous

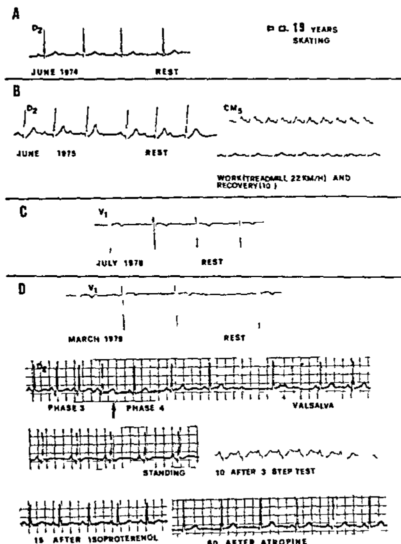

Fig 1 Case 2 World ranking skater *A* First control tracing after 3 years of sports activity normal ECG at rest *B* One year later Wenckebach phenomenon at rest is observed A V conduction is completely normalized during exercise *C* Three years later Wenckebach A V block is not appreciable *D* March 1979 Wenckebach A V block at rest A V conduction is normalized by Standing exercise isoproterenol and atropine administration Valsalva phase 4 induces an abrupt appearance of Wenckebach second degree A V block without a significant reflex sinus bradycardia There is transient shifting of the atrial pacemaker after atropine

ability of A V conduction pattern (Figs 1 to 3) mainly in relation to the intensity of training but the progression to advanced or fixed complete heart block has never been documented

All athletes at the time of our investigation were well trained and were completely asymptomatic Family and personal histories were accurately taken Furthermore since athletes are frequently motivated to minimize their symptoms whenever possible we tried to obtain the athletic history from their coaches Physical examination echocardiogram and phonocardiogram were taken in all subjects Echocardiographic findings diagnostic of mitral valve prolapse (MVP)[23, 8] were present in Cases 8 9 and 10 Cases 9 and 10 additionally had a variable mid systolic click Despite repeated auscultations no murmurs or clicks were found in Case 8 (silent prolapse)[29] None of these athletes had physical features characteristic of Marfan s syndrome[30] even if Patient No 9 was 6 feet tall

Reflex autonomic tests After informed consent to protocol study had been obtained in all athletes a basal standard ECG was recorded after 15 minutes rest in the recumbent position with a multichannel Hewlett Packard electrocar

In assessing an abnormal sinus node function the following experimental criteria were utilized

1 A sinus arrest lasting more than 3 seconds after vagal maneuvers

2 An inadequate sinus rate increase after physical exercise

3 Isoproterenol test

a A sinus rate increase of less than 20 b/minute

b A shifting of the atrial pacemaker or emergence of a junctional rhythm

4 Atropine test[31, 3]

a A percent shortening of the basal sinus cycle length of less than 30%

b A target rate of less than 90 b/minute

c A heart rate increase sustained by non sinusal pacemakers

In assessing an abnormal atrioventricular node function the following criteria were uti

Results (Table II)

Reflex autonomic tests Vagal maneuvers induced significant slowing of sinus rate in six cases (Nos 2 4 5 6 9 and 10) and had minimal or no effects in the remaining four In Case 8 EP *caused a high degree A V block* (Fig 4)

RCSP and LCSP induced an abrupt or progressive remarkable lengthening of PR interval with maintenance of 1 1 nodal A V conduction in Cases 4 and 8 suggesting a dual pattern of nodal A V conduction[11,12] (Figs 4 and 5) Sinus node response to Valsalva followed a *physiological*

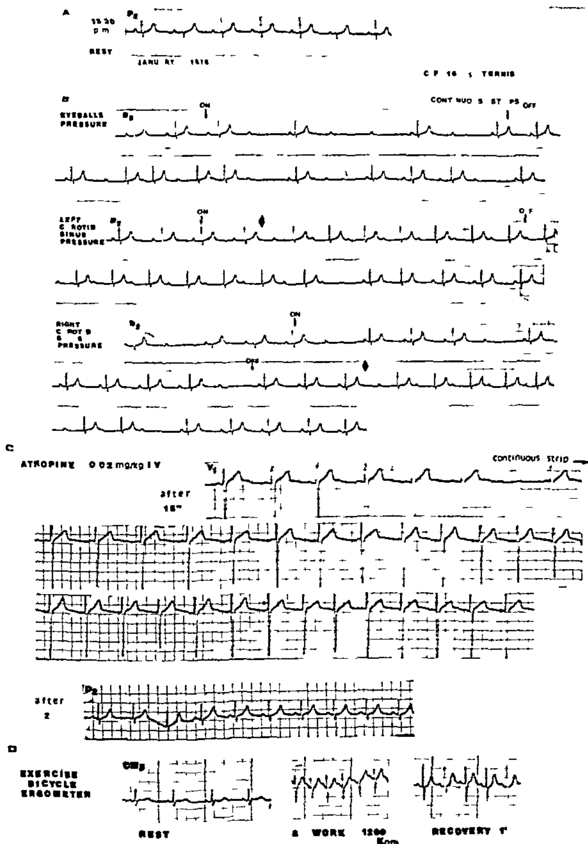

Fig 4 For legend see facing page

of sinus node to Standing was quite variable ROHV and/or Standing normalized A V conduction in eight cases (Nos 1 2 3 5 6 8 9 and 10) and improved it in Cases 4 and 7

Pharmacological tests Isoproterenol induced the expected increase of sinus rate in all cases This drug normalized A V conduction in all cases except one (Case 7 Fig 6) in which a Wenckebach A V block arose when sinus rate reached 90 b/minute In Case 4 a reduced response of sinus node to atropine was observed because of a target rate of less than 90 b/minute and a percent shortening of basal sinus cycle length inferior to 30%

Atropine induced a transient shift of the atrial pacemaker in Case 2 (Fig 1) and the occurrence of an accelerated junctional rhythm with complete or incomplete atrioventricular dissociation in Cases 1 8 and 10 (Fig 4) Sinus node response to atropine was within normal limits in the remaining five cases Atropine normalized A V conduction in all cases (Figs 1 to 6)

Exercise All athletes achieved the maximal age predicted heart rate in response to the highest workloads The physical performance of each of our athletes was adequate to his degree of training (Case 10 sustained a maximum workload of 2300 Kpm —375 Watts—on the bicycle) VO max values were over 45 ml /kg /min in all cases with a peak value of 71 ml /Kg /min in Case 3

None of the subjects showed ST and T wave abnormalities and arrhythmias during effort Exercise induced the complete disappearance of ventricular premature beats even at low work loads in Case 10

Work normalized A V conduction in all subjects except one (Case 7 Fig 6) in whom a transient Wenckebach phenomenon of nodal conduction was observed at a heart rate of 125 beats/minute

Follow up studies Case 8 was seen again 11 months after the study when he was still well trained ECG at rest was unchanged and A V conduction anomalies immediately and completely disappeared after sympathetic reflex stimulations and exercise Case 6 (Fig 3) was seen again in March 1979 1[illegible] months after our study when he had been inactive for [illegible] month because of an ankle trauma [illegible] at rest evidenced a 1 1 A V conduction [illegible] normal PR duration which was not influenced [illegible] reflex vagal stimulations

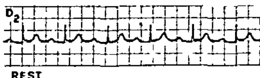
Valsalva phase 4 induced an abrupt change of the atrial pacemaker The last control examination in July 1979 after 5 months of inactivity confirmed the complete disappearance of A V conduction abnormalities and the persistence of an induced shift of the atrial pacemaker

Discussion

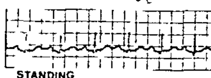
The introduction of intracardiac electrophysiological investigations has allowed a precise localization of sites of A V conduction disturbances and a better definition of the prognosis of different types of A V blocks[23] [4] On this regard the occurrence of Wenckebach second degree A V block in apparently normal persons [1] and in trained athletes [14] has been regarded as a vagally mediated functional disturbance of impulse conduction localized to the A V node and considered a benign clinical event

Unfortunately this optimistic view has been recently questioned by Young and associates[7] who found the possible evolution of Wenckebach type second degree A V block to advanced or complete block in adolescents without clinical *findings of cardiac disease* Those authors also pointed out that neither a positive response to exercise and atropine nor the results of the electrophysiological investigations can be considered reliable prognostic indexes However Hanne-Paparo and co workers[16] described a case of a 30 year old sportsman with Wenckebach A V block who had been followed for 10 years without evidence of progressive deterioration of A V conduction

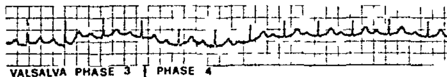
More recently Murayama and associates,[2] showed that ECG changes observed in 102 Japanese olympic ranking athletes (Tokio Olympic Games 1964) during the competitive period (including first and second degree A V block) completely disappeared in 95% of subjects within 4 years from the end of physical activity



Our study seems to be in full agreement with the observations of Hanne Paparo and colleagues and Murayama and associates for the following reasons



1 The favorable follow up studies of six of our athletes



2 The characteristic spontaneous variability of A V conduction pattern in relation to the intensity of training or forced *detraining* (Figs 1 2 and 3)

MAY 1979 D V 27 YEARS

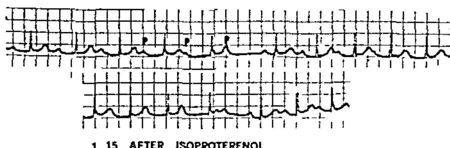


Fig 6 Case 7 Professional soccer player First-degree A V block at rest Worsening of A V conduction up to Wenckebach second-degree A V block after Step Test and isoproterenol administration After atropine 1 1 A V conduction with a PR interval of 0 18 sec is observed

behavior[11] in Cases 6 and 10 Valsalva phase 4 induced a sinus arrest of 1 8 seconds followed by junctional escape beats and premature atrial beats in Case 9 (Fig 2) in Case 5 a short period of sinus arrest interrupted by a single junctional escape beat and followed by regular sinus rhythm was observed The remaining six cases (Nos 1 2 3 4 7 and 8) did not show any slowing of sinus rate during Valsalva phase 4 (Figs 1 and 6) Valsalva phase 4 induced a Wenckebach type second degree A V block in Cases 1 and 2 (Fig 1)

Valsalva phase 2 and 3 completely normalized A V conduction in seven cases (Nos. 2 3 5 6 8 9 and 10) (Fig 1 to 3) in Cases 1 and 4 (Fig 5) it improved Wenckebach second degree block to first degree block while it caused only a small shortening of PR interval duration in Case 7 (Fig 6) An adequate increase of sinus rate during ROHV was observed in all subjects The response

block does not seem indicated provided that

1 They are asymptomatic

2 A complete noninvasive cardiological examination shows the absence of any cardiac pathological involvement

3 An immediate normalization of A V conduction pattern can be obtained with reflex sympathetic stimulations sympathomimetic or vagolytic drugs and physical exercise

Wenckebach second degree A V block in asymptomatic athletes with MVP features probably does not affect the prognosis if normal responses to the aforesaid provocative tests are observed

Summary

The occurrence of Wenckebach second degree (Mobitz I) A V block in apparently normal persons still provides a puzzle for the cardiologist as the benign nature of this event has been recently questioned This problem becomes more intriguing when Wenckebach A V block is encountered in asymptomatic top ranking athletes, because of medico legal implications We report 10 cases of highly trained athletes including three with mitral valve prolapse (MVP) features with a spontaneous or induced Wenckebach second degree A V block

Previous ECGs of six subjects dating from a maximum of 6 years to a minimum of 18 months were available Deterioration of A V conduction has never been documented and all six cases have remained asymptomatic for the whole follow up period

Athletes have been submitted to a protocol study consisting of ECG recording at rest during and after vagal and sympathetic reflex maneuvers drug administration (isoproterenol and atropine) submaximal and maximal exercise

Nine subjects have been considered to have normal responses of the A V node to provocative tests since conduction disturbances were improved or normalized by reflex sympathetic stimulations and were completely normalized by autonomic drug administration and exercise

One athlete showed abnormal responses to tests In ord[illegible]ive a conclusive prognostic and medico leg[illegible]ment we advised him to submit to a[illegible] electrophysiological investigation

Wenck[illegible]ond degree A V block in athletes may be a more common finding than so far described, especially when a systematic search is made In our opinion this event can still be considered a vagally induced benign feature of athlete s heart provided that an immediate improvement of A V conduction is obtained in response to reflex sympathetic maneuvers and that a complete normalization after sympathomimetic and vagolytic drug administration and physical exercise is observed

The clinical histories of our athletes and the observed complete disappearance of conduction disturbances after detraining strongly support this opinion

Wenckebach second degree A V block in asymptomatic athletes with MVP features probably does not affect the prognosis if similar favorable responses to the aforesaid tests are observed

We are grateful to Dr Antonio Greco for providing facilities and continuous encouragement in our studies We also thank Prof Antonio Venerando for his scientific assistance in processing the manuscript and Mr G Madeddu for his secretarial assistance We are additionally indebted to Dr Sima Sandric Dr Fernando Cecchetti and Dr Antonio Spataro for their help in evaluating the athletes

3 The significant improvement of A V conduction obtained even after simple sympathetic maneuvers and the complete normalization induced by autonomic drug administration and exercise in all athletes except one

Nevertheless abnormal responses of A V nodal conduction to isoproterenol and exercise were appreciable in Case 7 (Fig 6) In order to obtain a conclusive prognostic and medico legal assessment we advised this athlete to submit to an invasive electrophysiological investigation which up to now he has refused

Functional vagogenic depression of A V nodal conduction in athletes seems therefore confirmed by our observations However a hyporeactivity of sinus node to vagal maneuvers as evidenced by the lack of significant reflex sinus bradycardia during Valsalva phase 4 and abnormal responses of sinus node to atropine administration have been observed in five cases (Nos 1 2 4 8 and 10, Figs 1 and 4) These events could suggest the possibility of sinus node dysfunction or sick sinus syndrome (SSS)[3, 34]

Nevertheless similar behavior after atropine administration has been reported in apparently normal persons of different ages especially in young subjects and when low doses of the drug were employed[1] The effects of different doses of atropine on S A and A V nodes have been recently investigated by Das and colleagues S A node response was characteristically bimodal as sinus rate slowed at smaller doses and accelerated at higher doses while A V node showed acceleration of conduction whatever the dose of atropine administered

The above mentioned authors suggested that like any other receptor blocking agent[1] atropine can produce a transient stimulating effect namely a vagomimetic response Therefore the simultaneous occurrence of sinus bradycardia and A V conduction facilitation could be explained by the different electrophysiological effects of acetylcholine on the rates of impulse formation and impulse conduction Moreover the appropriate sinus rate increase after isoproterenol infusion[31, 3] and exercise[3] seems to confirm the normality of sinus node automaticity in our athletes Therefore despite the recent report of Roland and associates we strongly doubt that at present our athletes could be affected by SSS On the other hand in spite of our apparently reassuring opinion long term follow up studies are mandatory in order to verify the possible role of heavy prolonged training in the pathogenesis of SSS at a later time in life

It now remains to explain why

1 A training mediated increase of vagal tone has induced in our athletes major A V conduction disturbances instead of sinus bradycardia which is the usual autonomic response of the heart to training[3, 11] and

2 The hyporeactivity of the sinus node to Valsalva and atropine administration exists in some of our athletes

As our subjects did not show any evidence of chronic degenerative diseases involving the autonomic nervous system[4, 50] a possible alternative explanation of the aforesaid findings could be found in an individually different distribution of the parasympathetic influence on S A and A V nodes in otherwise normal persons

Wenckebach second degree A V block and mitral valve prolapse in athletes MVP may be an unexpected finding in asymptomatic top ranking athletes[6, 7, 51, 5] In accordance with the findings of Barlow[53, 5] we previously suggested that in the assessment of the sports aptitude of athletes with MVP features a permissive criterium has to be adopted provided that no ventricular tachyarrhythmias at rest[55, 5] and during effort[3] have been observed However remarkable sinus bradycardia with syncopal episodes[5] and atrioventricular and intraventricular conduction disturbances[8, 60] have been recently reported in subjects with MVP but their pathogenetic clinical and prognostic implications are still questionable

In the present report the S A and A V nodes responses to provocative tests and the follow up studies of athletes with MVP did not differ from the results in normal athletes

Therefore in our opinion the occurrence of A V conduction disturbances in asymptomatic athletes with MVP features has to be regarded in the same manner as in normal sportsmen provided that these anomalies have shown normal responses to the aforesaid protocol study

Conclusions

Our observations support the opinion that a systematic aggressive diagnostic approach in athletes with Wenckebach second degree A V

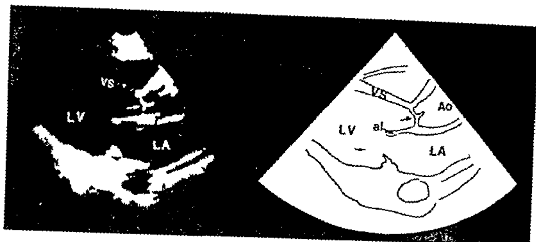

Fig 1 A left ventricular longitudinal cross sectional echocardiogram from a normal control depicting the left ventricle *(LV)* left atrium *(LA)* ventricular septum *(VS)* and the anterior leaflet of the mitral valve *(al)* *The white arrow s head* lies at the mouth of the aorta at the level of the aortic ring and points to the coaptation point (at mid aortic level) of the right and posterior aortic valve cusps in diastole The cusps lie well above the aortic ring

phases of the cardiac cycle were noted The coaptation point of the aortic cusps were analyzed for its degree of echo reflection and for its location and the presence of any diastolic motion M mode echocardiograms were analyzed for aortic root size location of the coaptation line in diastole echo reflectivity of the aortic cusps and for fluttering of the mitral and aortic valve leaflets

Study population A total of 112 consecutive patients with cross sectional echocardiographic criteria for mitral valve prolapse as previously described[13] were analyzed for morphological appearance and mobility of the aortic valve The longitudinal left ventricular cross sectional echocardiographic study was considered adequate for imaging the aortic valve only when two cusps were clearly seen and their motion and coaptation point could be visualized throughout diastole This demanded that the surrounding landmarks (the interventricular septum anterior mitral valve leaflet and aortic root) were well visualized M mode echocardiographic aortic root enlargement was considered present if the aortic root exceeded previously defined normal limits Cusp thickness was considered increased when one or both cusps reflected increased echoes from any part of the cusp compared to controls and from a target of known thickness in the same patient Downward displacement of the cusp tissue or coaptation point was assessed in real time and displacement was felt to be present when leaflet tissue or the coaptation point were imaged inferior to the aortic valve ring towa[rds] the left ventricular outflow tract Tricuspid v[alve] prolapse was defined using previously descri[bed] cross sectional echocardiographic criteria[11] [uti]lizing both the right ventricular longitudi[nal] inflow tract and apical views Severity of mit[ral] valve prolapse was determined using both l[eft] ventricular longitudinal and four chamber api[cal] views with severe mitral valve prolapse be[ing] present when the mitral leaflets moved w[ell] beyond the mitral ring level towards the l[eft] ventricular apex Mild prolapse was defined [as] minimal leaflet displacement beyond the mitr[al] valve ring and moderate was defined as bei[ng] between mild and severe

All studies were analyzed blindly by thre[e] echocardiographers on two different occasions The inter and intraobserver variability was les[s] than 5%

Results

Control population M mode echocardiographic aortic root measurement in 14 controls revealed normal aortic root size in all (mean 3 3 ± 0 3 cm [SD] range 2 8 to 3 8 cm) All subjects demonstrated the coaptation line of the two visualized aortic cusps in the center of the aortic root The two cusps appeared symmetrical with only a minimum of echo refractivity which established the normal degree of echo reflection Mitral valve fluttering (anterior leaflet) suggestive of aortic regurgitation was not seen in any of the control subjects and none of the 14 had any evidence of

Cross-sectional echocardiographic detection of aortic valve prolapse

The identification of aortic valve prolapse has been limited to surgical and pathological studies[1-3] Read and Thal[1] in 1965 identified at surgery the coexistence of aortic valve prolapse in patients with mitral and tricuspid valve prolapse The mucoid degeneration in the aortic valve appeared to be due to a diffuse connective tissue disorder involving the cardiac fibrous skeleton unrelated to aging M mode echocardiography[4] has been able to document mitral and tricuspid valve prolapse in part because of the larger atrioventricular annular and leaflet size rendering easy identification of the prolapsing motion Conversely the aortic annulus is smaller and aortic cusps less voluminous and less echo reflective and thus previous noninvasive identification of aortic valve prolapse has not specifically been defined Chandraratna and colleagues[9] reported a single case of aortic valve prolapse demonstrated at surgery in which the M mode echocardiography revealed diastolic aortic leaflet fluttering Rippe and co workers reported four patients who had marked aortic valve excursions on M mode echocardiography and were thought therefore to have aortic valve prolapse These patients clinically did have aortic regurgitation and mitral valve prolapse and thus aortic valve prolapse syndrome was suggested Cross sectional echocardiography provides real time evaluation of the aortic valve and thus this study was conducted to determine the prevalence and characteristics of aortic valve prolapse as defined by this noninvasive technique

Material and methods

All cross sectional echocardiographic studies were obtained using a wide angle 84 degrees commercially available phased array system (Varian V 3000) with a transducer containing 32 mounted piezoelectric crystals with a diameter of 1 3 × 1 2 inches at the skin level All studies were recorded on videotape (Sanyo) and were later reviewed in real time slow motion and frame by frame analysis Individual frame selections for figures were photographed using a Polaroid camera The quality of these still frame images was significantly degraded since only one half of the line density was present during the still framing M mode echocardiographic studies were obtained using a Smith Kline Echoline 20A with a 2 25 MHz transducer Left ventricular longitudinal and short axis views of the aortic valve were obtained using the conventional approach[12]

Control population Fourteen subjects (mean age 51 ± 10 years [SD]) with normal cardiac catheterization and cineangiographic findings were selected to define normal aortic valve morphology and motion characteristics by cross sectional echocardiography The thickness of the aortic cusps and their mobility during various

$p < 0 01$

mean age of 36 ± 21 (SD) years (11 were female) and revealed a different aortic valve morphology and motion characteristic compared to controls

Cross sectional echocardiographic findings In 16 of 17 patients the echo reflectivity from the aortic valve cusp tissue was considered increased compared to conrols The coaptation point of the aortic valve was considered eccentric by cross sectional echocardiographic analysis in six patients while the other 11 patients showed a central positioned coaptation point The six patients with eccentric coaptation all had three aortic valve cusps demonstrated on short axis tomographic view The eccentricity was noted to be anterior in four (Fig 2*A*) and posterior in two patients (Fig 2*B*) Real time motion assessment revealed that unlike the controls there was downward displacement of both aortic cusps during diastole in 13 of the 17 patients whereas two cases had isolated right or posterior cusp

Sixteen of 17 patients with aortic valve prolapse demonstrated evidence of tricuspid valve prolapse on the right ventricular longitudinal inflow tract and/or apical four chamber view The other case demonstrated a normal tricuspid valve but only an apical view was available In 31 (52%) of the 60 subjects with mitral valve prolapse but without aortic valve prolapse tricuspid valve prolapse was demonstrated (p = NS) Longitudinal left ventricular and apical views were used to assess the severity of mitral valve prolapse The severity of mitral valve prolapse in the 17 patients with aortic valve prolapse (six mild five moderate six severe) was not statistically different from that seen in the 60 cases with mitral valve prolapse without aortic valve prolapse

M mode echocardiographic and clinical findings There was no aortic root enlargement visualized by M mode echocardiography in any of the 60 patients with mitral valve prolapse without aortic valve prolapse mean aortic root diameter was 3 1 ± 0 3 cm (SD) Aortic root size was enlarged in six of 17 patients with aortic valve prolapse the mean for all 17 patients was 3 5 ± 0 5 cm (SD) Evidence of anterior mitral leaflet fluttering compatible with aortic regurgitation was seen in four of 17 and in three of the four physical examination revealed a diastolic murmur compatible with aortic insufficiency One patient had moderate aortic regurgitation by aortic root angiography with three aortic valve cusps Three of these four patients had evidence of aortic root enlargement on M mode echocardiography whereas three of 13 without aortic regurgitation showed aortic root dilatation Two of these four patients had diastolic aortic valve separation and fluttering as previously described [10] Two of the 17 patients had abnormal diastolic echoes from the prolapsed aortic valve protruding into the left ventricular outflow tract similar to that described by El Shahawy and co workers [16] Table I contrasts those patients with and without aortic valve prolapse

Discussion

This cross sectional echocardiographic study has suggested the presence of aortic valve prolapse in 17 (22%) of 77 patients with mitral valve prolapse Aortic valve morphology and motion characteristics were clearly altered in these 17 patients compared to a control population of normal subjects and to 60 patients (78%) of the group selected with mitral valve prolapse Unfortunately the striking real time echocardiographic findings noted in these patients cannot be reproduced on still photographies as used in the representative Figs 1 and 2 The 17 patients with aortic valve prolapse showed higher degrees of aortic valve thickening eccentricity of aortic cusps and a higher prevalence of clinical aortic regurgitation and M mode echocardiographic aortic root dilatation

Carter and co workers[3] have classified aortic

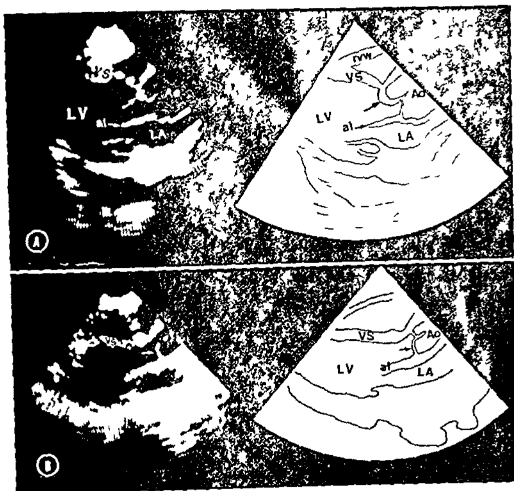

Fig 2 *A* A left ventricular longitudinal cross sectional echocardiogram from a patient with aortic valve prolapse demonstrating the left ventricle *(LV)* aorta *(Ao)* left atrium *(LA)* anterior mitral valve leaflet *(al)* and the right ventricular wall *(rvw)* *The head of the white arrow* lies well into the left ventricular outflow tract at mid mitral valve level and points to a marked prolapse and asymmetry of the right aortic valve cusp *B* A left ventricular longitudinal cross sectional echocardiogram from a patient with aortic valve prolapse demonstrating the left ventricle *(LV)* left atrium *(LA)* aorta *(Ao)* and the anterior mitral valve leaflet *(al)* *The white arrow* points to a prolapsed thickened and asymmetric large posterior aortic valve cusp

mitral valve prolapse Cross-sectional echocardiographic evaluation revealed a central coaptation point of the two aortic cusps and relatively faint echo reflection as viewed from the left ventricular longitudinal section Real time analysis of the aortic valve closure pattern in diastole with subsequent frame by frame analysis revealed that the coaptation point of the two cusps remained fixed throughout diastole and that there was no downward displacement towards the left ventricle during diastole The aortic cusps were slightly convex towards the center of the aorta at the level of their coaptation point Fig 1 demonstrates a typical example of a normal aortic valve closure pattern during diastole

Still photos demonstrated in this manuscript are limited to show the striking real time echocardiographic findings since the aortic valve cusps tended to be *relatively* poor echo reflectors and therefore their position was difficult to demonstrate when only one half of the line density was present on stop frame images

Study population The aortic valve was adequately visualized for analysis in 77 of 112 (68%) patients with cross sectional echocardiographic evidence of mitral valve prolapse Sixty (78%) of these 77 patients had a mean age of 38 ± 18 years (SD) and in all 60 the aortic valve characteristics and motion features were identical to those of the 14 controls These patients were considered to have mitral valve prolapse without aortic valve prolapse The remaining 17 patients (22%) had a

changes in patients with aortic valve prolapse is present Previously reported surgical experience[1, 17] suggests that a subgroup of cases exists with aortic mitral and tricuspid valve prolapse in which valvular regurgitation may require prosthetic valvular replacement

The inability of M mode echocardiography to visualize and detect superoinferior prolapsing motion of aortic valve produces serious limitation for this technique in the detection of aortic valve prolapse However few features on M mode echocardiographic tracings may suggest the presence of aortic valve prolapse The presence of increased aortic valve reflections eccentricity of the diastolic closure line aortic root enlargement abnormal diastolic echoes in the left ventricular outflow tract and the presence of fluttering of the anterior mitral leaflet can all be used to suggest the possibility of coexistence of aortic valve prolapse in patients with mitral valve prolapse

The limitations of this cross sectional echocardiographic study are clear First the true prevalence of adequate visualization of the aortic valve cannot be assessed from this study since it was performed in a retrospective manner in selected patients with mitral valve prolapse referred to our echocardiographic laboratory, and thus may not be applicable to population studies in patients without mitral valve prolapse Second the analysis of a study populaton of mitral valve prolapse for the detection of aortic valve prolapse may create bias as to the actual spectrum of aortic valve prolapse The possibility of the presence of aortic valve prolapse without mitral valve prolapse cannot be excluded from this study In addition we have no data comparing the actual clinical manifestations and natural history of patients with aortic valve prolapse compared to those patients with mitral valve prolapse without aortic valve prolapse Nevertheless this study demonstrates the potential of cross sectional echocardiography to diagnose a subgroup of patients with mitral valve prolapse with specific aortic valvular abnormalities suggesting the coexistence of aortic valve prolapse The potential of evaluating the prevalence of aortic valve prolapse in a populaton with aortic insufficiency has not yet been explored

Summary

To determine the potential for cross sectional echocardiography to define aortic valve prolapse 14 controls with a mean age of 51 ± 10 years (SD) with normal cardiac catheterization were studied by cross sectional echocardiographic left ventricular longitudinal and short axis views to define normal aortic valve morphology and motion characteristics Similarly, 112 patients with cross sectional echocardiographic mitral valve prolapse were analyzed to determine aortic valve morphology and motion characteristics In all 14 controls the left ventricular longitudinal view revealed the aortic valve as a faint echo reflector with symmetrical cusps whose closure point as well as the cusp tissue itself did not display any downward (or prolapsing) motion toward the left ventricular outflow tract In the group of 112 patients with mitral valve prolapse, the aortic valve was successfully imaged for detailed analysis in 77 Sixty of these 77 (78%) had a mean age of 38 ± 18 years (SD) and revealed aortic valve morphology motion characteristics similar to controls All of the remaining 17 patients (mean age 36 ± 21 years 11 female) revealed a downward displacement (or prolapse) of the aortic valve during diastole There was an increased echo reflection from the cusp tissue in 16 of 17 and in six of 17 cusp size was asymmetric producing eccentricity of the coaptation point All six of these had three aortic cusps seen on the short axis view The aortic root size was normal in all controls in the 60 patients with mitral valve prolapse without aortic valve prolapse whereas six of 17 patients with aortic valve prolapse had aortic root enlargement When comparing the group with (N = 17) and without (N = 60) aortic valve prolapse the tricuspid valve was prolapsed in 16 of 17 compared to 31 of 60 (p = NS) and aortic insufficiency was present in four of 17 compared to none of 60 ($p \leq 0.01$)

In conclusion cross sectional echocardiography can identify a subset of patients with mitral valve prolapse who have aortic valve prolapse in which aortic root dilatation and aortic regurgitation may be encountered Such patients may reflect a more diffuse myxomatous degeneration of the cardiac skeleton

valvular prolapse into etiologies associated with intact cusps, ruptured cusps, loss of commissural support, and ventricular septal defect with displacement of the aortic root. The patients in our study all had intact cusps as defined by echocardiography since none had evidence of serious cardiovascular disease such as dissecting aortic aneurysm, ventricular septal defect, or traumatic or infected aortic valve or aorta. Causes of intact cusps with aortic valve prolapse include (1) intrinsic weakness due to "floppy valve syndrome" with or without dilatation of the aorta, (2) fraying of a cusp[1] characterized by thinning without through and through laceration which may result in the affected cusp ballooning in an aneurysm-like faction towards the ventricle, and (3) excessive aortic valve tissue in patients with a congenital bicuspid aortic valve.[3]

Pathologic and surgical evidence of aortic valve prolapse due to "floppy valve syndrome" has been suggested.[1,3,11,16] Read and colleagues[1] in 1965 reported the existence on histology of myxomatous transformation of the cardiac valves in surgical patients and suggested the term "floppy valve syndrome." These patients, they suggested, may represent a possible forme fruste of Marfan's syndrome. No specific etiologic basis was identified. Seven cases of aortic valve prolapse were defined surgically by Frable,[2] and McKay and Yacoub[17] reported that 9% of 560 patients who underwent mitral or aortic valve replacement had myxomatous degeneration of the mitral and/or aortic valve. Eleven had isolated aortic valve prolapse and nine of these were men.

Previous echocardiographic studies[9, 6] to define aortic valve prolapse have been limited to M mode technique and none could be considered diagnostic or specific for aortic valve prolapse. Real time visualization of the aortic valve using cross sectional echocardiography in which a superoinferior direction of the aortic valve can be analyzed is required to establish this diagnosis noninvasively. Due to the relatively small aortic ring and cusps area, cross-sectional echocardiographic analysis to detect aortic valve prolapse requires meticulous review of the real time study. The redundancy of a cusp with diastolic motion towards the left ventricular outflow tract has been our operational definition of aortic valve prolapse. The sensitivity and specificity of this technique cannot be evaluated due to the lack of a "gold standard" for prolapse valves, but we believe that the abnormal aortic valve morphology and motion characteristics in our subgroup of patients with mitral valve prolapse, when compared to controls, is an acceptable definition for this entity. Further support is provided by the increased prevalence of aortic root dilatation and clinical aortic insufficiency in this subgroup of patients.

Six of our 17 patients with aortic valve prolapse had aortic cusp eccentricity probably due to myxomatous degeneration affecting one cusp more severely. These patients must be differentiated form those with congenital bicuspid aortic valve disease. In bicuspid aortic valve disease one cusp is usually larger and has been called the conjoined cusp.[3] The conjoined cusp may prolapse on the basis of excessive tissue relative to the distance between the two commissural attachments. The differentiation between aortic valve prolapse on the basis of the "floppy valve syndrome" or bicuspid aortic valve disease[3] may be possible using the short axis view of cross sectional echocardiography. Using this view, the presence of three separate aortic cusps would tend to exclude the presence of a bicuspid valve and, in fact, all six of our patients with an eccentric aortic cusp had three aortic valve cusps using this approach. This unfortunately does not entirely prove the absence of a bicuspid aortic valve since an uncommon form of congenital bicuspid aortic valve exists in which the center of the free edge of the conjoined cusp is joined to the aortic wall by a thin strand. This might give the impression of a tricuspid aortic valve.[3] However, since our patients were drawn from a population of patients with mitral (and often tricuspid) valve prolapse and since all six did have an apparent tricuspid valve on the short axis view, and one patient had a tricuspid aortic valve on angiography, we believe the majority, if not all of these cases did in fact have aortic valve prolapse on the basis of the "floppy valve syndrome."

In addition, this study suggests that not only congenital bicuspid aortic valves may cause eccentricity of the aortic valve closure line in diastole on M mode echocardiography,[18] but that aortic valve prolapse caused by the "floppy valve syndrome" should be considered. Though not statistically significant, the increased prevalence of tricuspid valve prolapse in patients with aortic valve prolapse suggests that a more widespread involvement of the myxomatous degenerative

Mitral valve prolapse in anxiety neurosis (panic disorder)

Alagiriswami Venkatesh, M D
David L Pauls Ph.D
Raymond Crowe M D
Russell Noyes Jr M D
Charles Van Valkenburg M D
James B Martins M D
Richard E Kerber M D
Iowa City Iowa

The typical symptoms of anxiety neurosis or panic disorder—palpitation dyspnea chest pain and dizziness—suggest a cardiovascular disturbance and in the past led to such labels as irritable heart ' effort syndrome and neurocirculatory asthenia [1] Similar symptoms may be reported by patients with the recently described syndrome of mitral valve prolapse In fact panic disorder and mitral valve prolapse share a number of clinical features Both are common disorders probably affecting 5% to 10% of the population both are frequent in young women and both may be familial [1] The characteristic physical findings of mitral prolapse a mid systolic click and late systolic murmur have not been associated with panic disorder in the past but these sounds were in general not felt to be of clinical significance until Barlow and co workers[3] demonstrated their relationship to the prolapsing mitral valve

The [illegible] ities between panic disorder and pr[illegible] [illegible]ed Wooley[4] to suggest that many pat[illegible] [illegible]d as having panic disorder might be [illegible] mitral valve prolapse Pariser and associates[5] described several such cases The purpose of this study was to test Wooley's hypothesis in a group of rigorously diagnosed patients with panic disorder

Methods

From 112 anxiety neurosis patients followed by Noyes and Clancy [6] we selected 20 patients for this study on the basis of (1) meeting Feighner and colleagues'[7] research criteria for anxiety neurosis (panic disorder) and (2) for convenience living within 100 miles of Iowa City Feighner and colleagues'[7] criteria for the diagnosis of anxiety neurosis (panic disorder) are (1) age of onset prior to 40 (2) chronic nervousness with recurrent anxiety attacks (manifested by apprehension fearfulness or sense of impending doom) occurring at times other than during marked physical exertion or life-threatening situations and in the absence of medical illness or other psychiatric illness There must have been at least six anxiety attacks each separated by at least a week from the others and (3) at least four of the following symptoms (a) dyspnea or a choking or smothering sensation (b) palpitations (c) chest pain or discomfort (d) dizziness (e) paresthesia All 20 patients who met these criteria and lived within 100 miles of Iowa City were contacted and all 20 agreed to participate One family was doubly ascertained through a mother and daughter both with panic disorder leading to a total of 21 index subjects These 15 women and six men ranged in age from 21 to 62 years with a median of 37 An

prolapse plus click murmur and/or exercise induced PVC s Within the panic disorder group patients with mitral valve prolapse determined by echocardiogram and those without prolapse had a similar incidence of clicks and/or murmurs and electrocardiographic abnormalities

Discussion

In this study eight of 21 panic disorder patients had echocardiographic evidence of mitral prolapse Seven of these had auscultatory or electrocardiographic findings suggestive of the mitral prolapse syndrome in addition to echocardiographic demonstration of prolapse Of the two control subjects with echocardiographic evidence of prolapse only one showed additional abnormalities on auscultation or electrocardiogram Thus mitral prolapse was identified significantly more often among the panic disorder patients than among the controls ($p < 0.05$) This finding suggests that a substantial number of patients bearing the psychiatric diagnosis of panic disorder also have an organic abnormality mitral valve prolapse

The panic disorder patients in this study were selected solely on the basis of meeting diagnostic criteria for panic disorder and also by geographic proximity to the medical center However they were part of a larger group which had originally been selected from patients referred to the University of Iowa Clinics This raises the question of whether the larger group contained patients with abnormal cardiac findings who might have been preferentially referred for evaluation The possibility of such a selection bias was assessed by reviewing the original patient records This revealed that most had been referred to the Internal Medicine and Neurology Clinics for evaluation of symptoms which their referring physician thought might have been associated with physical disease Heart murmurs were noted at the time of the original evaluation in only four patients and none were considered at that time to have symptoms of cardiac origin

Although we were able to demonstrate prolapse in many of these panic disorder patients the simultaneous occurrence of these conditions does not necessarily imply a causal relationship Why patients with mitral prolapse develop symptoms such as chest pain dyspnea and palpitations cannot at this time be answered It is conceivable that both panic disorder and mitral prolapse are manifestations of some underlying disorder as yet undefined

Although this study is a preliminary one the results support the link between anxiety neurosis or panic disorder and the mitral valve prolapse syndrome as proposed by Wooley[4] Patients with symptoms of panic attacks should be suspected of having the mitral prolapse syndrome Echocardiography electrocardiography and stress testing are diagnostically useful in such patients

Summary

Our purpose was to determine the incidence of mitral valve prolapse in patients with anxiety neurosis or panic disorder with symptoms including recurrent anxiety attacks dyspnea palpitations chest pain dizziness and paresthesias Twenty one patients and 20 age and sex matched normal controls were studied Objective cardiac abnormalities were significantly ($p < 0.05$) more frequent in the patient group as compared to the control group these comprised echocardiographic prolapse ST T abnormalities

age and sex matched control group was selected from hospital employees There were 14 women and six men with a median age of 37 (range 23 to 62 years) This group was specifically free of anxiety symptoms and denied a history of heart disease

The study was approved by the Human Research Committee of the University of Iowa informed written consent was obtained from all participants

A medical history was obtained from all subjects with specific questioning for symptoms of panic disorder A physical examination was performed by a cardiology fellow During the cardiovascular examination systolic clicks and murmurs were sought by auscultation in the supine and upright positions Resting and exercise electrocardiograms were obtained using the Bruce exercise protocol Echocardiograms were performed on all patients using a Smith Kline Ekoline 20A ultrasonoscope with a 2 5 mHz transducer focused at 7 5 cm and a Honeywell 1856 fiberoptic strip chart recorder The mitral valve recordings were obtained by positioning the transducer perpendicular to the chest wall as recommended by Popp and co workers

The echocardiographic criteria for mitral prolapse were those of Markiewicz and colleagues[1] The points of coaptation (C point) and separation (D point) were identified and a line was drawn between the two (C D line) Echocardiographic prolapse was considered to be present if the predominant systolic mitral echo extended more than 2 mm posteriorly from the C D line either in a smooth concave hammock shaped fashion (holosystolic prolapse) or as a sharp mid late systolic buckling The echocardiograms were read by an observer who was not otherwise involved in the study and who did not know if the recording was from an index subject or a control

Left ventricular diameters were measured at end diastole (R wave of ECG) and end systole (smallest distance between posterior wall and septum) Left atrial diameters were measured at end systole

Results

The results are summarized in Table I Ten panic disorder patients had systolic clicks and/or murmurs on auscultation Of these murmurs two were holosystolic five were mid late systolic one was early systolic and one was variable between examinations Two patients had mid late systolic clicks (one of these also had a murmur) No patient had skeletal abnormalities associated with mitral valve prolapse such as pectus excavatum

Seven patients showed ST T wave abnormalities on resting electrocardiograms two of these seven patients were taking tricyclic antidepressant drugs which may have caused or contributed to these electrocardiographic findings No patient developed angina or ST T changes with exercise all but one achieved 85% of the age predicted maximum heart rate One patient had premature ventricular contractions (PVC s) at rest nine had PVC s with exercise (one had PVC s occurring in couplets during exercise)

Systolic prolapse was demonstrated by echocardiogram in eight panic disorder patients four holosystolic and four mid late systolic Of the eight panic disorder patients with echocardiographic evidence of prolapse five had clicks and/or murmurs and two others had PVC s on exercise Only one patient with echocardiographic evidence of prolapse had no additional abnormality

Six control subjects had systolic clicks and/or murmurs (Table I) On auscultation two had holosystolic murmurs and one had a mid late systolic murmur Four patients had mid late systolic click (one of these also had a murmur) One control subject had PVC s at rest and another developed them with exercise Three control subjects developed ST T changes with exercise but none experienced angina Two had echocardiographic evidence of prolapse one holosystolic and one mid late systolic Of these two control subjects with evidence of prolapse one had a systolic click and resting PVC s while the other had no additional abnormality

Echocardiographically determined left ventricular and left atrial volumes and left ventricular minor axis shortening (ΔD) were normal for both groups There were no significant differences between the groups in these measurements.

Differences between groups were assessed for significance using Fisher s exact test or in the case of echocardiographic diameters a Student s t test was used (Table I) Patients with panic disorder had a significantly higher incidence of echocardiographically demonstrated prolapse resting electrocardiographic ST T abnormalities exercise induced PVC s and echocardiographic

Evaluatıon of left atrıal thrombus wıth computed tomography

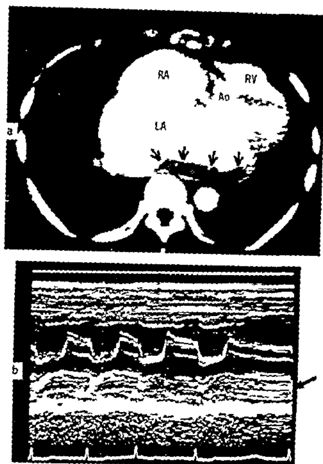

Fig 3 A patient with mitral stenosis-regurgitation atrial fibrillation and two histories of cerebral thromboses (Case No 3) *A* computed tomogram at the level of the left atrium a thrombus (7 5 cm × 1 7 cm × 3 cm) is indicated by *arrows* *RA* = right atrium *RV* = right ventricle *Ao* = aorta *LA* = left atrium *B* echocardiographic findings in the same patient (the thrombus is indicated by an *arrow*)

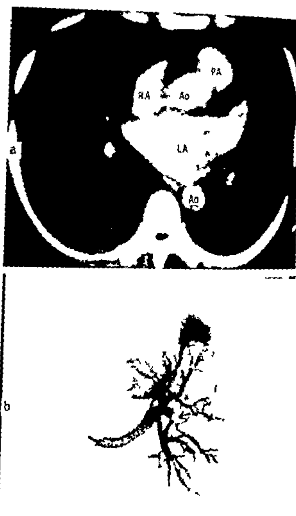

Fig 4 A patient with mitral stenosis regurgitation at fibrillation and a history of renal thrombosis There i thrombus lodged in the dorsal branch of the left renal art as indicated by an *arrow* *(B)* but there is no left at thrombus demonstrated with computed tomography *(A)* C diac surgery subsequently performed also revealed no l atrial thrombus *RA* = right atrium *Ao* = aor *PA* = pulmonary artery *LA* = left atrium

Hg pulmonary capillary wedge—15 mm Hg (mean) and aorta—106/64 mm Hg

The left ventricle was not entered via the retrograde route due to severe aortic stenosis Cineangiographic findings (levophase pulmonary arteriography and aortography) revealed mitral stenosis aortic stenosis with regurgitation and enlarged left atrium There was an insufficient filling of the left atrial appendage which suggested a thrombus in the area of the left atrial appendage

Computed tomograms at the left atrial level revealed two spherical thrombi—one located at the atrial appendage with a tomographically measured size of 2 0 cm × 2 3 cm and another located at the right posterior wall of the left atrium with a measured size of 2 0 cm × 2 9 cm (Fig 2) She was operated on for valve replacement and a total of 20 gm of left atrial thromb which were consistent with the shapes and sizes detected by computed tomographic method was excised

Patient 3 A 68 year old woman presented with mitral stenosis regurgitation atrial fibrillation and with two previous episodes of cerebral thromboses and another episode of bilateral femoral arterial thrombosis Right heart catheterization was performed and intracardiac pressures were as follows right atrium—5 mm Hg (mean) right ventricle—40/5 mm Hg pulmonary artery—50/20 (mean 30) mm Hg and pulmonary capillary wedge—26 mm Hg (mean) A levophase pulmo-

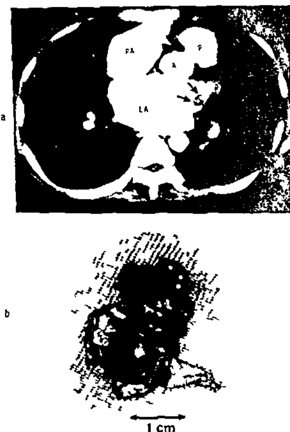

Fig 1 A patient with mitral stenosis regurgitation tricuspid regurgitation, and atrial fibrillation (Case No 1) *A* computed tomogram at the level of the left atrium a thrombus (1 3 cm × 1 6 cm) is indicated by *arrows* *RA* = right atrium *RV* = right ventricle *Ao* = aorta *LA* = left atrium *B* surgically excised thrombus of the same patient (3 5 gm)

Fig 2 A patient with mitral stenosis regurgitation aortic stenosis regurgitation atrial fibrillation and a history of cerebral thrombosis (Case No 2) *A* computed tomogram at the level of the left atrium a thrombus (? 0 cm × 2 3 cm) is shown by an *arrow* at the atrial appendage *B* another thrombus (? 0 cm × 2 9 cm) is indicated by an *arrow* at the right posterior wall of the left atrium which is ? cm lower than the appendage level *SVC* = superior vena cava *Ao* = aorta *PA* = pulmonary artery *LA* = left atrium

findings of the patient were compatible with mitral stenosis minimal regurgitation and tricuspid regurgitation but no left atrial thrombus was detected echocardiographically

Intracardiac pressures were as follows right atrium–6 mm Hg (mean) right ventricle–90/7 mm Hg pulmonary artery–97/37 (mean 58) mm Hg pulmonary capillary wedge–24 mm Hg (mean) left ventricle–124/13 mm Hg and aorta–129/79 mm Hg Cineangiographic findings (levophase of pulmonary angiogram and left ventriculogram) revealed thickened and stenosed mitral valves grade 1 mitral regurgitation, and a markedly enlarged left atrium but no thrombus was detected cineangiographically

On the other hand computed tomography at the level of the left atrium indicated a filling defect in the left atrial appendage measured as 1 3 cm × 1 6 cm on the tomogram (Fig 1*a*) Open mitral commissurotomy was performed 4 days after the computed tomographic evaluation and a well-organized thrombus of 1 cm × 1 5 cm × 2 cm (weight 3 5 gm) was found in the left atrial appendage and was excised (Fig 1*b*)

Patient 2 A 47 year old woman presented with mitral stenosis regurgitation aortic stenosis regurgitation and atrial fibrillation She had a history of cerebral thrombosis a year ago with persistent right hemiplegia Phonocardiographic and echocardiographic findings were compatible with the above diagnoses and the presence of left atrial thrombi was suspected echocardiographically Intracardiac pressures were as follows right atrium–4 mm Hg (mean) right ventricle–34/3 mm Hg pulmonary artery–35/16 (mean 23) mm

results with computed tomography in 13 patients who subsequently underwent cardiac surgery Computed tomography is essentially noninvasive and appears to be one of the best methods to evaluate left atrial thrombus

nary arteriogram revealed an enlarged left atrium with a thrombus located at the posterior wall of the left atrium

Computed tomographic findings demonstrated a large left atrial thrombus measuring 7 5 cm × 1 7 cm (the height was estimated as an average of 3 cm) located at the posterior wall of the left atrium (Fig 3a) The thrombus attached to the posterior wall of the left atrium was easily demonstrated echocardiographically as shown in Fig 3b The computed tomographic findings were confirmed by autopsy performed 3 months after the tomographic evaluation and the weight of the thrombus was approximately 40 gm

Discussion

Detection of left atrial thrombi in patients with mitral valvular diseases is of significant importance regardless of the size of the thrombi because the patients are always faced with the possibility of systemic embolization Parker and colleagues have demonstrated that atrial thrombi were predicted correctly angiographically in six out of 70 patients who subsequently had cardiac surgery but thrombi could not be detected in two patients Echocardiography is noninvasive and one of the most hopeful methods for detecting atrial thrombi in patients with mitral valvular diseases

Recently Mikell and associates demonstrated atrial thrombi correctly by two dimensional echocardiography and the minimum thrombus detected echocardiographically as a spherical aggregate approximately 1 5 cm in diameter

On the other hand due to the limitation in the direction of echo beam projection small thrombi located in the left atrial appendage or in the right edge of the left atrium are difficult to detect echocardiographically[2] Computed tomography has the advantage of offering uniform slices of the left atrium in an attempt to detect thrombi in unknown areas of the left atrium The method is not disturbed by the presence of the ribs or thoracic cage as in the case of echocardiography

Both fresh and organized thrombi were delineated with computed tomography and the nature of the thrombi might be possible to estimate by the difference in the x ray transparency i e the CT numbers In Case No 1 the thrombus was mostly organized with partial fibrosis and the CT number was +68 In Case 2 the thrombi were almost fresh without fibrosis and the CT number was +42 which was identical to that of the left ventricular chamber (+40) The CT number was not recorded in Case 3

The minimum size of the thrombi detected tomographically was 3 5 gm as shown in Case 1 but the lowest limit of the thrombus size which can be detected is still not known although there is the possibility that an extremely small thrombus might be missed by any method In another 51 year old woman with mitral stenosis regurgitation and atrial fibrillation an episode of renal thrombosis was encountered 6 days before the tomographic evaluation and a thrombus 0 2 cm × 0 4 cm in size and lodged in the dorsal branch of the left renal artery was demonstrated angiographically

However there was no left atrial thrombus apparent in computed tomography and cardiac surgery performed subsequently did not reveal a left atrial thrombus which appeared to have been washed out completely (Fig 4) Therefore there have been no false negative or false positive cases experienced so far

The stop action method gated with ECG is possible in the system used in the present study[7] but our impression is that the quality of the tomogram is not satisfactory due to reduced data sampling numbers for every frame of the tomogram Therefore it should be noted that the configurations of the various cardiac structures obtained by computed tomography are affected by the effects of cardiac movements Fortunately however the cardiac movements are relatively limited at the cardiac base especially in enlarged atria with fibrillation

Computed tomography is a noninvasive method and based on our experience in a limited number of patients it appears to be one of the best methods in evaluating left atrial thrombi to determine the details necessary for medical or surgical treatment

Summary

Left atrial thrombi were evaluated with computed tomography in 23 patients with mitral valvular diseases In three of the patients left atrial thrombi were delineated with computed tomography and were confirmed by cardiac surgery or autopsy The minimum size of the thrombi detected tomographically was 3 5 gm

There were no false positive or false negative

ılthough the clinical course and prognosis of ıatients with acute myocardial infarction has ıeen carefully studied little attention has been ıiven to the effect of age on mortality rate

In this paper we present the age sex and ıospital mortality rate and analyze the factors nfluencing prognosis in a group of patients aged '0 years and older with acute myocardial infarc ion A comparison is made with the mortality ate of all patients less than 70 years of age who ıere admitted during the same time period

ʾatients and methods

The elderly study group (Group A) included all ıatients admitted to the coronary care unit of ʾiedmont Hospital between May 1 1971 and Ianuary 31 1977 who met the following crite ıa

1 age 70 years or greater

2 a diagnosis of acute myocardial infarction (MI) on the *basis of any two of the following* three factors—

a prolonged chest discomfort compatible with myocardial injury

b characteristic electrocardiographic changes of myocardial infarction including serial ST T changes or the development of pathologic Q waves

c elevation of serum creatine phosphoki nase (CK) to at least two times the upper limits of the normal range

A total of 175 patients met two or more of these criteria All patients were observed in the coro nary care unit with continuous monitoring No drugs were given routinely without specific indi cations Data were obtained in a retrospective manner from a comprehensive data base acquired at the time of admission on all patients to the coronary care unit as well as from a review of physician s office records prior to admission A prior history of angina pectoris myocardial infarction diabetes mellitus hypertension (sys tolic BP equal to or greater than 160/90 mm Hg) and congestive heart failure was noted The phy sician s office records did not always contain the physician s specific diagnostic criteria therefore this information was considered as historical information and consequently does not meet rigid standards of definition Serial electrocardiograms (ECG s) were evaluated to determine the electro cardiographic site of the myocardial infarction and the presence or absence of a conduction defect Shock was defined as a systolic blood pressure of 90 mm Hg or less associated with a urine output of less than 20 c c /hr Complica tions occurring during the AMI were determined from a review of the hospital record the detailed data base compiled during the admission and a review of all ECG s and chest films reports The cause of death was determined from the hospital record or autopsy reports

Group B was composed of 772 patients below age 70 with acute MI who were admitted to the hospital during the same time period The age and sex related hospital mortality rate of this younger age group was compared with the study group

Results

There were 175 patients in Group A—83 (47 4%) were male and 92 (52 6%) were female Table I shows the age sex and mortality rate per decade

of the deaths due to anterior MI The major cause of death in the 16 patients with inferior MI was shock in four patients (25%) and sudden death in three (18 8%) accounting for 43 8% (seven of 16) of the 16 deaths due to inferior MI

The ten patients with autopsy documented external cardiac rupture had several distinguishing characteristics The sex was predominantly female (seven of 10) Nine of the ten patients had no history of prior MI The cardiac rupture generally occurred during the first 48 hours of hospitalization (seven of 10) and was within 60 hours of the onset of symptoms in the seven cases There were seven ruptures of the anterior wall two of the inferior wall and one rupture of the apex This distribution paralleled the distribution of the myocardial infarctions in the entire study group (anterior MI 66 9% inferior MI 33 1% Table IV) The location of the external myocardial rupture was always in the site of the acute myocardial infarction as determined by ECG and as noted at autopsy

There were nine patients who died suddenly without autopsy Four of these nine patients sustained a final clinical event that was marked by sudden cardiorespiratory arrest with a bradycardia observed on the ECC monitor and with absent pulses on physical examination Myocardial rupture was suspected in these four patients The remaining five patients who died suddenly were not monitored at the time of death and the cause of the final event was not apparent

Discussion

Patients with myocardial infarction in the age group 70 and older differ in their sex distribution clinical course and hospital mortality rate when compared to patients younger than age 70 In this study of 175 patients aged 70 and older the male female ratio was 0 9 1 0 (Table I) In contrast the male female ratio of our 772 patients under age 70 admitted during the same time period was 2 77 1 0 while under age 60 the male female ratio was 3 85 1 0 In reported series of patients less than 70 years of age there is a striking male preponderance Fitzgerald[2] studied 865 patients with acute MI and found the male female ratio to be 7 1 below age 50 10 1 between age 50 and 59 and 4 1 in the age group 60 to 69 Following a peak in the sixth decade male preponderance declines rapidly until the eighth decade when the male female ratio approaches 1 1 in most large series[1]

The prevalence of certain prognostic factors in the age group 70 years and older is higher than the incidence of similar factors reported in younger age groups Frank[5] studied 881 men aged 25 to 64 who had their first MI The incidence of angina pectoris was 17% hypertension was 25% congestive heart failure was 4% and diabetes mellitus was 11%[5] In our elderly group of patients the incidence of angina pectoris was three times hypertension was 1 8 times congestive heart failure was five times and diabetes mellitus was two times the incidence in the study by Frank (Table IV) A history of prior MI was present in 33 3% of our patients This is similar to the 28% to 38% prevalence of prior MI reported in several studies of younger patients[6-10]

The increased prevalence of these prognostic factors in our elderly group was not however associated with an increased mortality rate (Table II) There were no prognostic factors present in 23 5% of the survivors or in 16 1% of the nonsurvivors (Table III) The mortality rate of patients with zero one two three and four prognostic factors represented a random distribution (Table III) Hospital mortality rate was not influenced by the number of prognostic factors present in individual patients (Table III) nor by the over all prevalence of prognostic factors in the entire study group (Table II)

Factors that significantly influenced hospital mortality rate from acute MI were the development of shock pulmonary edema on chest x ray a clinical diagnosis of congestive heart failure and the development of complete heart block or new bundle branch block during the hospital course ($p \leq 0\ 01$ Table IV) These complications are usually associated with the loss or dysfunction of a significant amount of ventricular muscle from the new or any prior MI In this study there was a significantly high mortality rate of 88 9% associated with complete heart block ($p = 0\ 001$ Table IV) Although all three of the patients with new BBB died the hospital mortality rate associated with the presence of BBB in general including BBB known to be present prior to the acute myocardial infarction was not significantly increased ($p = 0\ 26$ Table IV) This discrepancy may be due to the high incidence of pre-existing BBB on the basis of Lev s or Lenegre s disease in the elderly[11-13] Bundle branch block related to these causes may not signify the same degree of muscle necrosis or ventricular dysfunction as BBB resulting from acute myocardial infarction

tic factors per patient (p = 0.25 by Chi square analysis).

Hospital course. The serial ECGs and hospital course of the 175 elderly patients were reviewed to determine whether or not factors could be identified which were associated with increased hospital mortality rate. The mortality rate of patients with anterior MIs (32.7%) was not significantly different from that of patients with inferior MIs (30.2%, Table IV). The development of either complete heart block or a new bundle branch block on the ECG was associated with a high mortality rate (Table IV). Eight of the nine patients (88.9%) with complete heart block died despite temporary cardiac pacing. Complete heart block was associated with an anterior MI in five patients (55.6%), inferior MI in three patients (33.3%), and an undetermined site in one patient. Twenty-one patients had a bundle branch block, a right bundle branch block (RBBB) was present in ten, and a left bundle branch block (LBBB) was present in 11 (Table IV). The development of a new bundle branch block (BBB) during the hospital course was documented in only three patients (1.7%) all of whom died. There were 18 patients with BBB on the admission ECG, nine of these 18 cases could be documented as being present previously. On admission to the hospital one patient had a LBBB which subsequently resolved. The remaining eight cases of BBB were of unknown duration. The mortality rate of all patients with old or new BBB was 42.9% (nine of 21). Five of the 56 patients who died had RBBB and four had LBBB.

Cardiogenic shock, pulmonary edema on chest x-ray, CHF by examination, and complete heart block occurring on admission or during the hospital course were all associated with a significant mortality rate ($p < 0.01$, Table IV). The presence of shock either on admission or developing during the hospital course was associated with an 80% mortality rate (24 of 30). Pulmonary edema documented on chest x-ray and occurring at any point during the hospital course was associated with a 60% mortality rate (15 of 25). Congestive heart failure (CHF) as defined by rales, jugular venous distention, and/or a ventricular gallop was associated with a mortality risk of 39.6% (42 of 106).

Hospital deaths. The records of the elderly patients dying in the hospital were analyzed to determine the specific cause of death (Table V). The over all hospital mortality rate was 32% (56 of 175). The major cause of death was shock

Table III. Comparison of the number of prognostic factors in survivors and nonsurvivors

		Number of prognostic factors						
		0	1	2	3	4	5	Total
Survivors	No.	28	23	38	19	9	2	119
	%	23.5	19.3	31.9	16	7.6	1.7	
Non survivors	No.	9	16	13	14	3	1	56
	%	16.1	28.6	23.2	25	5.4	1.8	
% mortality according to the number of prognostic factors present		24.3	41	25.5	42.4	25		

accounting for 33.9% (19 of 56) of the deaths. Of the 19 patients who died of shock, 13 of 19 had anterior infarctions (68.4%), four of 19 had inferior infarctions (21.1%), and two of 19 had an undetermined site of infarction (10.5%). Mitral regurgitation was present in three of the four patients with shock related to an inferior infarction. The inferior MI was associated with a prior anteroseptal MI in the remaining patient.

External cardiac rupture was documented in 10 of 23 patients studied at autopsy (Table V). This represented 17.9% of the 56 deaths and was the second major cause of death. Sudden death (unwitnessed and unmonitored) accounted for an additional nine deaths representing 16% of the total mortality. A significant number of these deaths may have been cardiac rupture (discussed below), however autopsies were available on only two of the nine. The remainder of the deaths were due to severe CHF (six patients—10%), arrhythmia (four patients—7.1%), GI bleeding (two patients—3.6%), aspiration (one patient—1.8%), and aortic dissection (one patient—1.8%). Two patients (3.6%), one with an anterior and one with an inferior MI, developed ventricular septal rupture and both died postoperatively following surgical repair. The cause of death could not be determined from the record in two cases (3.6%, Table V).

The major cause of death in the 35 patients with anterior MI was extensive muscle damage. This was manifested by shock in 13 of the 35 cases (37.1%) and severe CHF in five of the 35 cases (14.3%) (Table V), accounting for 51.4% (18 of 35)

Table V Causes of death related to electrocardiographic site of infarction

MI = myocardial infarction CHF = congestive heart failure LBBB = left bundle branch block GI = gastrointestinal Ant = anterior Inf = inferior

of cardiac rupture The incidence of cardiac rupture in documented acute MI s has been reported to be 3 8% to 27%[21 25] Most series have reported an average incidence of about 10%[21 23 26] An increased incidence of cardiac rupture has been found in the elderly and in females[26-29] The majority of cardiac ruptures are reported to occur during the first 3 days following the onset of the symptoms of acute MI[22 23 30] Cardiac rupture occurred during the first 48 hours of hospitalization and within 60 hours of the onset of symptoms in 70% of our autopsy-documented cases In this study 70% of the patients with cardiac rupture had definite transmural MI s and the remaining 30% had acute MI s of undetermined extent at the time of death from cardiac rupture The association of external cardiac rupture with a first MI (nine of 10 patients in this study) is attributed to the absence of significant collateral vessels and fibrosis in the area of acute infarction where the rupture develops [2]

The hospitality mortality rate from an acute MI in the elderly group of 175 patients was 32% (Table I) This was 3 9 times greater than the mortality rate of 8 2% in our younger group The mortality rate reported in several studies in the literature for predominantly younger hospitalized patients with MI (age 70 and younger) is 8% to 20% (average 15%)[1 23 31 34] The explanation for the increased mortality rate in the elderly has not been well defined There is a higher incidence of associated prognostic factors i e previous MI shock CHF etc in elderly patients Russek and Zohman[35] divided patients above and below 60 years of age into good risk and poor risk groups Two thirds of the patients 60 years and older were shown to be poor risks compared to 47% of patients less than 60 years of age[35] There was no significant difference in mortality rate between the older and younger groups when the risk factors were comparable Russek and Zohman concluded that age itself was not an independent risk factor Our findings differ from theirs and indicate that age is a significant independent prognostic factor When the mortality rate in our good risk elderly group (patients with no prognostic factors Table III) is compared to the mortality rate of our younger patients (Group B) with and without prognostic factors the mortality rate in the good risk older age group is 2.7 times that of the entire younger age group (24.3% vs 8.9%) Age therefore is a significant independent prognostic factor even when the "good risk" older patients are compared with younger patients

Per cent mortality calculated by formula $\frac{\text{No. of non survivors}}{\text{No. of non survivors + survivors}}$

Other studies however have shown an increased mortality rate associated with complete heart block and BBB whether present prior to an acute MI or developing in association with an acute MI[1, 6]

Cardiogenic shock was the major cause of death in this series of hospitalized patients The electrocardiographic location of the MI did not influence mortality rate since anterior and inferior MIs were associated with similar mortality rates (32.7% and 30.2% respectively Table IV) Pump failure (shock + CHF) was the major cause of death in patients with anterior and inferior MIs (Table V) A larger percentage of patients with anterior MIs (16.8%) compared to inferior MIs (9.4%) died from pump failure Anterior MIs potentially result in the loss of a larger mass of myocardium than do inferior MIs and are often associated with more severe myocardial dysfunction[7]

Inferior MIs occurred in 53 patients and were associated with shock in four patients (Table V) In three of these four patients papillary muscle dysfunction probably contributed to the shock In the fourth patient the inferior MI was associated with a prior anterior MI Isolated inferior MIs without prior anterior MIs and without papillary muscle dysfunction were not associated with shock

The second most common cause of death was external cardiac rupture (17.9% Table V) The incidence of autopsy documented cardiac rupture was 17.9% (10 of 56) in this study in which the autopsy rate was 41% (23 of 56) An additional two patients suffered a ruptured ventricular septum and died postoperatively The inclusion of these two patients brings the total incidence of cardiac rupture causing death to 20.7% Cardiac rupture may have occurred in an additional four patients in whom the clinical signs of cardiac rupture—sudden chest pain and or unconsciousness which is associated with apnea absent peripheral pulses an unobtainable blood pressure and the rapid development of a sinus or junctional bradycardia—were observed but autopsy confirmation was not obtained (Table V)[2] When these four patients are added to the ten patients with autopsy documented cardiac rupture and the two patients with a ruptured ventricular septum the incidence of cardiac rupture in this series becomes 28.6% This is over two and one half times the incidence of cardiac rupture reported in most series and suggests that the elderly dying of acute MI have a higher incidence

the elderly may be related to the high incidence of coexisting pathological processes which could contribute to pump failure[37, 38] Pathological changes occurring with aging include myocardial fibrosis aortic and mitral valve degenerative changes and calcification senile cardiac amyloidosis and presbycardia[37, 39] The high incidence of myocardial rupture in the elderly may also be a result of the chronic pathological changes that affect the aged myocardium In this sense advanced age is indeed a potent nonmodifiable risk factor that is associated with a high mortality rate[25]

Summary

The history and clinical course of 175 patients aged 70 and older (Group A) with acute myocardial infarction (MI) was studied to determine the hospital mortality rate in this population group and to determine the clinical factors that influenced the hospital mortality rate The mortality rate of a second group of 772 patients below age 70 years (Group B) admitted during the same time period was determined for comparison with the mortality rate in Group A

The hospital mortality rate in Group A (32%) was 3 9 times the hospital mortality rate in Group B (8 2%) Advanced age was associated with a significantly higher mortality rate even when so called good risk patients from Group A were compared with patients in Group B

The major causes of death in this hospitalized group of patients aged 70 and older were shock (33 9%) and cardiac rupture (28 6%) Factors that significantly influenced hospital mortality rate in the elderly group were the development of shock pulmonary edema on chest x ray a clinical diagnosis of congestive heart failure and the development of complete heart block or new bundle branch block during the hospital course

The authors express their grateful appreciation to the Piedmont Hospital Coronary Care Unit nurses for their help in data collection We also wish to thank Drs Robert C Schlant and J Willis Hurst for their constructive comments and Mrs Pat Kirby for her secretarial skills

for capillary fluid exchanges calculated as COP LVEDP is observed (Table IV) decreasing from a mean 8 4 mm Hg to a slightly negative gradient of –0 3 mm Hg Forty four per cent of this shift in gradient is accounted by the changes in COP (3 8 of 8 7 mm Hg)

Discussion

It is well recognized that an intravascular bolus injection of contrast media may precipitate acute pulmonary edema[5, 9] The observed expansion in plasma volume at two minutes after injection is consistent with other similar studies[2, 3] and represents an acute plasma expansion of 8 to 10 ml for each milliliter of hyperosmolar solution injected

The LVEDP elevation is well recognized as a major cause of pulmonary edema[18, 19] Almost a century ago Starling[2] suggested that intravascular colloids promote fluid absorption from the interstitial space at the microcirculatory level Guyton and associates and other workers[22, 23] subsequently presented quantitative evidence to substantiate the importance of the relation between left atrial pressure and plasma protein concentration on the development of pulmonary edema Since the more extensive availability of instruments for clinical measurement of COP the clinical importance of oncotic pressure in the evolution of pulmonary edema has been better defined[14] Stein and co workers[2, 25] presented evidence for pulmonary edema formation in the absence of left ventricular failure if the oncotic pressure is significantly decreased Da Luz and associates[12] showed that pulmonary edema may appear in the absence of a significant increase of the left ventricular filling pressure after acute myocardial infarction if the oncotic pressure is significantly decreased leading to an almost abolished gradient for capillary fluid exchanges In the critically ill patient the gradient for capillary fluid exchanges represents a much better predictor of pulmonary edema than the isolated measurement of LVEDP an abolished gradient representing a major risk of pulmonary edema whatever the LVEDP[10, 11, 6, 26] The hemodilution hypervolemia induced by a bolus injection of contrast media increases the LVEDP and simultaneously decreases the COP level Those changes invert (positive to negative) the gradient for capillary fluid exchanges resulting in a pulmonary edema prone situation It should be noted however that the relative importance of the decrease in COP and the increase in LVEDP varies from patient to patient in relation to the magnitude of the LVEDP changes The variations in COP are relatively fixed and determined by the volume changes

We conclude from this study that after a bolus injection of contrast media the total intravascular pressure changes predisposing to pulmonary edema are almost equally shared by the hydrostatic and oncotic pressure changes These findings further clarify the mechanism of pulmonary edema induced by contrast media

Summary

Angiographic contrast media are known to induce alterations in cardiovascular dynamics which may result in acute pulmonary edema The risk of pulmonary edema was previously shown to be negatively correlated to the level of colloid oncotic pressure (COP) It was also shown that the gradient between COP and left ventricular end diastolic pressure (LVEDP) represents a better predictor of pulmonary edema than does LVEDP alone The present report evaluates the effects of a bolus injection of contrast media on those pressures as predisposing factors for pulmonary edema

Our data are based on 15 unselected patients admitted for coronary angiography The plasma volume increased by 16 5% (2 903 to 3 384 ml) a

Effects of angiographic contrast media on colloid oncotic pressure

Left ventriculography requires a rapid injection of hyperosmolar contrast material into the arterial side These agents are known to decrease myocardial contractility [1,2] and cause a rapid increase in blood volume and cardiac output The general risk of pulmonary edema is 0 08% in all angiographic procedures [3,6] This risk may be significantly higher in patients with a compromised ventricular function [7,8] The problem of pulmonary edema has been attributed to an increased circulating blood volume and filling pressure The importance of acute hypervolemia on the oncotic pressure of plasma and edema formation even if suspected remains to be evaluated and quantified It is recognized that COP is inversly correlated to the risk of pulmonary edema [ ] Also it has been demonstrated that the risk of pulmonary edema is better predicted by the gradient for capillary fluid exchanges represented by the difference between colloid oncotic pressure (COP) and left ventricular end diastolic pressure (LVEDP) than by LVEDP alone In the present study the effects of a bolus injection of contrast media on COP and on the COP LVEDP gradient are examined

Material and methods

The group consisted of 15 unselected patients admitted for elective coronary angiography It included eight males and seven females with a mean age of 53 5 years (Table I) The patients were studied in the fasting state and received 10 mg diazepam orally as premedication From 40 to 60 ml of meglumine diatrizoate (Renographin 76%) was injected in 2 5 to 4 seconds for the left ventricular angiogram

A single injection of radioiodinated human serum albumin (RI[1] [3]SA) was used for determination of the three sequential plasma volumes [1] They were measured before at two and at 30 minutes following the injection of contrast material

COP was measured on plasma by the use of a transducer membrane system representing a modification of the technique of Prather [15] Weil [16] [ ] and their colleagues Arterial blood was obtained at the same time as plasma volume sampling

Results

The sequential changes in plasma volume following injection of contrast media are summarized in Table II A 16.5% increase in plasma volume is observed at two minutes A return towards normal values is found at 30 minutes although a slight non significant elevation still remains compared to the baseline

The COP response is shown in Table III Contrasting the increase in plasma volume a significant fall in plasma COP (16 2% $P < 0\,001$) is observed In 30 minutes the COP has returned to the control level

The end diastolic pressure significantly increases (Table III) at two minutes in parallel with the changes in plasma volume

A significant shift ($P < 0\,001$) of the gradient

two minutes after injection of a 50 c.c. bolus of meglumine diatrizoate (Renographin 76%) and had returned towards normal at 30 minutes. In parallel the COP decreased from 23.4 ± 2.4 to 19.6 ± 2.3 mm Hg ($P < 0.001$) to return the 22.7 ± 2.6. The COP LVEDP gradient decreased by 8.7 mm Hg (8.4 to −0.3, $P < 0.001$). Such a gradient was well within the danger zone of pulmonary edema. These findings further clarify the mechanisms of pulmonary edema induced by contrast media.

Despite sporadic interest in the lymphatic drainage of the myocardium the possibility that disordered lymphatic function contributes to tissue destruction following coronary artery occlusion has not been systematically examined During a study on the normal coronary lymphatic drainage we found that hyaluronidase had a striking influence on lymphatic visualization in the heart[1] Because hyaluronidase also has a clear influence on the evolution of myocardial necrosis after coronary occlusion[2,3] and because an unequivocal explanation for the mechanism by which hyaluronidase induces the salutary response is not available we undertook a systematic investigation into the lymphatic drainage of normal and infarcted myocardium and the impact of hyaluronidase on both The results are consistent with an important role of altered lymphatic drainage in the evolution of myocardial infarction and with a mechanism of hyaluronidase action which includes better sustained lymphatic drainage following myocardial infarction perhaps facilitating removal of high molecular weight toxic substances such as lysosomes from the ischemic myocardium

Methods and materials

Studies were performed in 48 mongrel dogs of either gender weighing about 20 kilograms Anesthesia was induced and maintained with sodium pentobarbital (30 mg /kg) and ventilation was maintained through an endotracheal tube with a Harvard respirator which provided 200 to 300 c c of room air/breath at a rate of 18 to 20/minute

Catheters were placed in the aorta from the right femoral artery for blood pressure monitoring and in the inferior vena cava from the right femoral vein for maintaining anesthesia In experiments during which the coronary artery was occluded without thoracotomy an additional catheter was placed via the left femoral artery in a superselective position in the left anterior descending or left circumflex coronary artery Coronary occlusion was accomplished in this way to avoid the possibility of venous or lymphatic obstruction which may occur when ligation is the method used to occlude the coronary arteries The artery was occluded with either a piece of Gelfoam (5 × 1 mm) or the tip of radiopaque polyethylene catheter using a modification of a technique described from this laboratory by Cohen and Eldh[4] All animals were killed at 24 hours and cardiac lymphangiography was performed immediately after death

1 Technique for cardiac lymphangiography Lymphatic vessels in the apical portion of the left ventricle were cannulated postmortem with a 30 gauge Becton Dickinson lymphangiography set using a 2 5 magnification lens The contrast agent utilized was made by adding 30 grams of barium sulfate to 3 to 5 ml of Iodamide 420 (Bracco Milan Italy) Five drops of food coloring were added to allow different colors for each lymphatic vessel The contrast agent was injected under gentle manual pressure until the lymphatic vessels were filled The heart was x rayed with

Fig 3 Lymphangiogram from dog pretreated with hyaluronidase Coronary arteries were patent in the dog

cm served as a single basic unit as it corresponded to 1 cm of ventricular myocardium (fivefold magnification was used for filming the lymphangiogram) Because of the 1 cm separation between the lines 25 crossings were present in each basic unit Each 1 cm on the grid corresponded to 2 mm of the venticular myocardium A point was counted whenever a crossing coincided with a vasualized lymph vessel in the lymphangiogram This approach provides *not a count* of lymphatic vessels but rather an index of their volume relative to that of ventricular myocardium The entire left ventricular surface was evaluated whenever point counts were obtained Following coronary occlusion the entire infarcted or noninfarcted zones were counted

Mean values have been presented with the standard error of the mean as the index of dispersion Statistical analyses were performed where appropriate with the Student t test The null hypothesis was rejected when P was less than 0 05

Results

1 Effect of *coronary* occlusion on lymphan*giograms* A typical normal myocardial lymphangiogram is shown in Fig 1 In the normal myocardium there was 1 64 ± 0 11 points/cm ventricle equivalent to 6 6% of the ventricular area (Table I) The variation from animal to animal was small as evidenced by a coefficient of variation of only 16 4%

Acute coronary occlusion induced striking statistically significant changes in the visualization of lymphatics on lymphangiography in both the infarcted zone and in the surrounding noninfarcted tissues In the infarcted zone (Fig 2 Table I) there was a marked reduction in the number of lymphatics visualized (0 90 ± 0 06 points/cm² ventricle 3 6% of ventricular area $p < 0.001$ vs normal) Conversely the noninfarcted zone showed a considerable increase in lymphatic visualization (2 81 ± 0 22 points/cm² ventricle 11 2% of ventricular area $p < 0.001$ vs normal)

2 Effect of hyaluronidase on lymphangiograms Hyaluronidase augmented myocardial lymphatic visualization in the normal dog In six normal dogs lymphatic density following hyaluronidase pretreatment was increased significantly (3 45 ± 0 18 13 8% of ventricular area $p < 0.001$ vs untreated normal myocardium) (Fig 3)

Hyaluronidase pretreatment resulted in improved visualization of lymphatics in the infarcted zones (5.22 ± 0 34 points/cm² ventricle 20 9% of ventricular area $p < 0.001$ vs

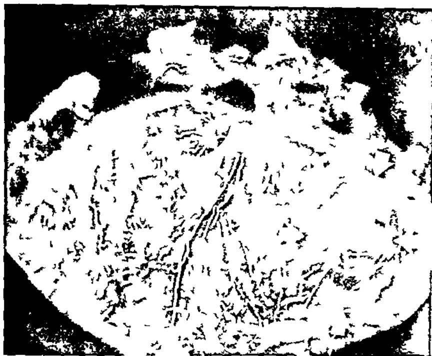

Fig 2 Lymphangiogram from dog with myocardial infarction following coronary occlusion *The arrows* indicate the ischemic zone

lymphatic trunk which measures approximately 1.5 mm in diameter was cannulated 2 to 3 cm above the left atrial appendage just before it enters the cardiac lymph node The catheteriza tion was accomplished with an angiocatheter (Intercath 22 gauge size Deseret Co Sandy Utah) after ligation of the lymphatic trunk to engorge the vessel

Lymph was collected in open tubes during free flow or with slight negative pressure for 2 hours prior to coronary occlusion and in 2 hour collec tions for 4 to 5 hours following coronary occlu sion Samples were collected on ice spun to remove visible blood cells and were frozen imme diately for bioassay the following day in four of the five experiments In the remaining experi ment the lymph was bioassayed immediately after the collection on ice

4 Bioassay of myocardial lymph The lymph samples were assayed in five normal dogs The left coronary artery was catheterized as described above the blood pressure and the ECG were continuously monitored

First the effect on the electrocardiogram of 1 0 ml of normal saline injected into the left coro nary artery of normal animals was evaluated for 10 minutes as a control As a second control lymph collected prior to coronary occlusion was injected as a 1 0 ml bolus and blood pressure and the electrocardiogram were monitored for 60 to 120 minutes Lymph obtained during the first 2 hours following coronary occlusion was then injected into the coronary artery of normal stable dogs and the animals were observed for 60 to 120 minutes Finally lymph collected during the second 2 hour interval following coronary occlusion was injected into the coronary artery of normal stable dogs and the animals were observed for an additional 4 to 6 hours

Following termination of the experiment lym phangiograms were obtained in all animals

In an additional three normal dogs with cardiac arrhythmias induced by placement of an electro magnetic flow meter probe around the coronary artery but in which no injections of any agent into the coronary artery were performed lym phangiograms were obtained to assess the contri bution of arrhythmias to lymphangiographic fea tures

5 Methods of analysis A grid was prepared to serve as an overlay on the fivefold magnified lymphangiograms allowing quantification of vi sualized lymphatics The grid considered of lines drawn at right angles 1 cm apart Each 5 × 5

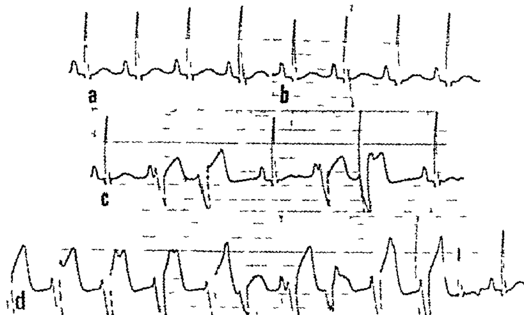

Fig 5 ECG changes in a normal dog following injection of saline *(a)* normal myocardial lymph *(b)* lymph obtained during the first 2 hours following coronary occlusion *(c)* and lymph obtained during the second ? hour interval following coronary occlusion *(d)*

occlusion The better sustained lymphatic system may be a cause or a consequence of favorable hyaluronidase influence on the course of tissue destruction If it were causal it might be assumed that the preserved lymphatics drain toxic material from the affected myocardium following coronary occlusion Our fourth observation is that indeed a factor toxic to the heart is found in lymph draining the myocardium following coronary occlusion

These observations permit three major lines of investigation to be integrated into a single conceptual framework An elegant series of studies has already implicated membrane damage and lysosomal enzyme release as participants in the development of tissue necrosis with ischemia [1] A second line of investigation has provided unequivocal evidence that hyaluronidase reduces myocardial necrosis following coronary occlusion but with no clear indication as to what the protective mechanism may be [2,12,19] Studies on lymphatic drainage from the hypoxic or ischemic heart have [illegible] that quantitatively important change [illegible] lymph flow occur and that obstruction [illegible] ic outflow has a pernicious influence on [illegible] of myocardial necrosis but have a[illegible] to define their over all contribution [illegible] volution of myocardial infarction [19] [illegible] king hypothesis is that lymphatic drainage is a determinant of tissue survival after coronary occlusion because toxic products possibly the products of damaged myocardial cells are removed via this route

What species of molecule is most likely to be drained primarily by lymphatics? For molecules of a size too large to allow easy access to the bloodstream via the blood capillary wall an important avenue of escape is likely to occur via the lymphatics Consistent with this concept three studies have demonstrated that enzymes such as creatine phosphokinase appear in myocardial lymph well before their concentration in blood rises following coronary occlusion [3,14]

Attention has been focused primarily on membrane disruption and evidence that lysosomal enzyme release occurs when the membranes become abnormal with considerably less attention paid to the role of the enzymes once they are released Certainly their local concentration and thus their toxicity must depend not only on their rate of release but also on the rate at which they are degraded or carried away Thus the transport and behavior of the enzymes and the compartments involved in their transport such as the interstitial space lymphatic vessels or coronary venous blood must also be considered Viewed in the perspective of our lymphangiograms following coronary occlusion perhaps it is not surpr-

Fig 4 Lymphangiogram obtained from dog pretreated with hyaluronidase and then subjected to coronary occlusion *The arrows* indicate the ischemic zone

untreated infarction) (Fig 4) There was no difference in the lymphatic density in the non infarcted zone in hyaluronidase pretreated and untreated dogs with coronary occlusion (2 65 ± 0 08 vs 2 81 ± 0.22)

3 Effect of cardiac lymph injections into the coronary arteries Saline and normal lymph injected into the coronary arteries induced no electrocardiographic changes (Figs 5*A* and 5*B*) Lymph collected during the first two hours following coronary occlusion induced relatively minor and transient electrocardiographic changes (Fig 5*C*) Lymph collected 2 to 4 hours following coronary occlusion induced in each case malignant arrhythmias in the normal dogs (Fig *5D)* In all cases the arrhythmias were delayed in onset first becoming evident in 10 to 15 minutes following injection and becoming progressively more severe Multifocal ventricular premature contractions were followed by ventricular tachycardia and ventricular fibrillation within 35 to 90 minutes following injection in three of the five dogs In the other dogs used for bioassay prolonged bouts of ventricular tachycardia subsequently reverted to normal rhythm with ST segment elevation > 3 mm at 6 hours following the injection of toxic lymph when the experiment was terminated

Lymphangiography demonstrated an increase in the number and size of visualized lymphatics present in each of the five dog hearts which had received toxic lymph injections into the coronary artery (4.3 ± 0.27 points/cm ventricle 17.2% of ventricular area $p < 0\,001$ vs normal) (Fig 6) No significant increase in lymphatic density could be detected in the three dogs with cardiac arrhythmias induced by mechanical stimulation (1 19 ± 0 11 points/cm ventricle 4.8% ventricular area p = NS)

Discussion

There are four new and probably related observations in this study which may shed light on the pathogenesis of progressive tissue destruction following coronary artery occlusion First a remarkable reduction in visualized lymphatic channels from ischemic myocardium occurs within 24 hours of coronary occlusion well before the disappearance of lymphatic vessels can be accounted for on the basis of coagulation necrosis Second hyaluronidase has a striking influence on the lymphatic vascular tree of the normal heart Third sustained integrity of the myocardial lymphatic system parallels the reduction in myocardial tissue destruction associated with hyaluronidase administered prior to acute coronary

necrosis one might anticipate substantial release of potassium and other small ions or organic moieties along with the intracellular protein re lease Detailed studies on the character of lymph draining the ischemic heart[27] and kidney[33] have detected little or no change in potassium or protein concentration The simplest explanation would appear to be that blood flow in the ischemic zones while markedly reduced, is still adequate to wash away the small molecules which easily diffuse into capillaries Whatever the explanation potassium and other small ions are not likely candidates as the toxic factor

The role of lymphatics in the evolution of tissue necrosis following coronary occlusion in the pro tective effect of hyaluronidase and in the clear ance of toxic factors from ischemic myocardium clearly requires more detailed evaluation Per haps the highest priority should be placed on identifying and characterizing the toxic material or materials a task which should be facilitated by what is clearly a very high concentration in the draining lymph As little as 0 5 ml injected into a healthy dog s coronary artery was lethal

Summary

Cardiac lymphangiography was applied to 29 normal dogs (ND) and 14 dogs following acute coronary occlusions In five of the ND lymph collected from infarcted dogs was selectively injected into the coronary artery prior to the lymphangiogram In ND the lymphatic density (LD) was 6 6% ventricular area (VA)

Acute coronary occlusion induced a change in the LD The infarcted zone registered a decrease in LD (3 6% of VA p < 0 001 vs ND) Hyaluroni dase increased LD in normal dogs (13 8% of VA p < 0 01 vs ND) Hyaluronidase pretreatment increased the LD in infarcted myocardium (20 9% of VA p < 0 001 vs non treated infarcts) No difference was seen between uninfarcted areas of treated and nontreated animals (10 6% vs 11 2% of VA) Lymph was collected from cardiac lym phatics in five dogs before and after coronary occlusion When selectively injected into coro nary arteries of ND post infarct lymph induced ECG changes of ischemia arrhythmias and increased the LD (14 6% VA p < 0 001 vs ND) The results suggest (1) Cardiac lymphatics are altered in the uninfarcted and infarcted zones following coronary occlusion (2) Hyaluronidase preserves the lymphatic density in infarction (3) Lymph collected from zones of infarction is toxic

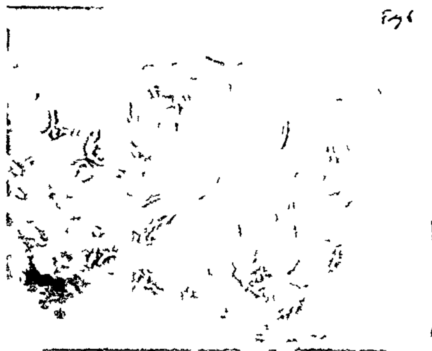

Fig 6 Lymphangiogram of left ventricle in a normal dog following the introduction of toxic lymph into the coronary artery

ing that lysosomal enzyme content of lymph following coronary occlusion was increased but that the increase was disappointingly modest An unstated premise in such studies is that the interstitium of the infarcting zone communicates freely with the draining lymphatic trunks a premise which now seems unlikely

How does hyaluronidase act to modify myocardial infarction? A number of suggestions including reduction of interstitial edema facilitation of perfusion via collateral blood flow and enhanced delivery of critical substrates through the interstitium have been made

Among the suggestions made the possibility that hyaluronidase might exert its salutary effect at least in part by increasing the washout of toxic metabolites has been raised but no direct evidence concerning this possibility was offered Some insight may be gained through close examination of the specific actions of hyaluronidase and the normal physiology of its substrate Hyaluronic acid is a viscous hydrophilic mucopolysaccharide of the connective tissue ground substance which holds the cells in its jelly like matrix by its viscosity In model systems of isolated proteoglycans the polysaccharide network has a negligible effect on the distribution and diffusion of oxygen water and sugars At physiological hyaluronic acid concentrations there is however measurable retardation in the diffusion of molecules as large as plasma proteins presumably because of steric restriction Hyaluronidase apparently facilitates diffusion of large molecules by enhancing the probability that a particle finds a path in the network through which it can move

From this analysis the possibility that hyaluronidase influences myocardial infarction by facilitating the delivery of small molecular weight substrates or oxygen seems less likely than that the diffusion of larger molecules such as protein is influenced critically Consistent with that action hyaluronidase has been documented as increasing lymphatic flow after intravenous injection in the dog[3]

What is the toxic substance likely to be? Because of normal lymphatic function toxic proteins perhaps lysosomal enzymes are likely candidates No direct evidence from this study is as yet available because it was necessary to utilize all of the small volumes of lymph collected for the bioassay to toxicity With the well-documented disruption of cell membranes which occurs during

Effects of circulatory arrest and rewarming on regional blood flow during surface-induced hypothermia

Judy Y Su, Ph D
David W Amory, Ph D , M D
Murray P Sands
H Mohri M D Dr Med Sci
Seattle Wash

Although intensive research efforts have clarified many aspects of hypothermic physiology the distribution of regional blood flow has remained obscure However the relatively recent development of a technology based on the use of nonrecirculating radioactive microspheres has made it possible to simultaneously determine regional blood flow throughout the body In a previous communication[24] we reported on the changes in distribution of cardiac output regional blood flow and vascular resistance during the cooling phase of a method of deep surface induced hypothermia developed in our laboratory and used as an adjunct for the correction of congenital cardiac defects in infants[2 ... 24] This report is intended to demonstrate the effects of induced circulatory arrest on regional blood flow and blood flow distribution during the rewarming phase of surface hypothermia

Materials and method

A detailed description of the operative procedure microsphere administration and radionuclide counting techniques has been provided in our previous report In summary catheters were inserted into the inferior vena cava abdominal aorta and left ventricle of 4 to 7 kg monkeys (*Macaca mulatta)* three days prior to the study On the day of the experiment control (awake) determinations were done Then the animals were anesthetized and surface cooled by our method[12 14] which includes the use of deep ether anesthesia in 100% O_2 artificial ventilation maintained at normal levels for normothermia so as to gradually induce respiratory alkalosis during cooling and the administration of 10 c c /kg of low molecular weight dextran (10% in D W) between 35° and 25° C during cooling

Five animals were cooled to 20° C rectal temperature maintained for 30 minutes and rewarmed by floating the animal on a plastic sheet over warm water (40° C) Another group of four animals were similarly cooled opened by sternotomy and a 30 minute period of circulatory occlusion was induced by crossclamping the cavae pulmonary artery and aorta Cardioplegia was accomplished by injecting 10 c c of Young's Solution* proximal to the aortic crossclamp Resuscitation was accomplished by manual cardiac massage and the administration of 300 mg of calcium chloride to neutralize the Young's Solution Defibrillation when necessary was by 50 volt AC electroshock Rewarming was started at the time of massage

At the end of each experiment the animal was exsanguinated and the major organs were removed weighed and placed in plastic vials for measurement of radioactivity The remainder of

*The values are means and standard errors of the means from five non arrested (NA) and four arrested (A) monkeys. and † denote $p \leq 0.05$ and ‡ denote $p \leq 0.01$ and ‡ denote $p \leq 0.001$. The statistical significances are shown in asterisks ( ) when the results are compared to that of unanesthetized control values by paired t test. The statistical significances are shown in daggers (†) when the results are compared between NA and A values by Student s t test. HR = heart rate MAP = mean arterial pressure CO = cardiac output SV = stroke volum TVR = total vascular resistance

(MAP) was significantly below control throughout rewarming in both groups however the MAP of arrested animals was significantly greater than non arrested animals at 20° 25° and 30° C Cardiac output in both groups was 30% of control at 20 C In the non arrested animals cardiac output increased steadily with rewarming to values not significantly different from control at 37° C Arrested animals displayed a similar trend until 30 C at 37 C output decreased slightly and was significantly below control In both groups stroke volume was not significantly different from control except for a decrease in the arrested group at the completion of rewarming (37° C)

Total vascular and organ resistance (Table I Fig 1) Total vascular resistance (TVR) was insignificantly reduced when compared to the control value in the non arrested group at 20° C during rewarming A decline to a significant degree was noted at 25 C that was maintained through the completion of rewarming The TVR of arrested animals was significantly reduced at 20 C following resuscitation but resistance increased to near control at 25 C declined again significantly at 30° C and was rising at the completion of rewarming (37° C) When the two groups were compared arrested animals had significantly higher TVR at 25° and 37° C

Cerebral vascular resistance was slightly greater than control at 20° C in non arrested animals but declined steadily during rewarming and a significant reduction to 65% of control was noted at the completion of rewarming The cerebral vascular resistance of arrested animals was considerably less at 20 C than in non arrested counterparts (75% vs 120% of control values) although the difference was not significant due to individual variation During rewarming cerebral group vascular resistance in the arrested group increased with temperature until 30 C and decreased slightly thereafter

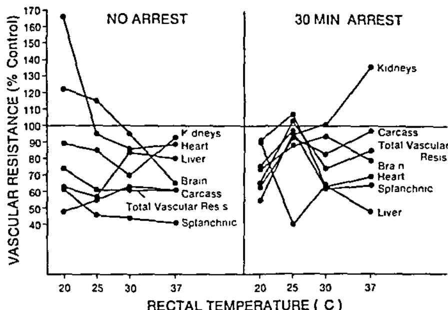

Fig 1 Total vascular and organ resistances plotted with the unanesthetized normothermic control value (not shown) as the 100% value

the body was ashed and a 20% aliquot of the mixed ash was also placed in vials for counting

Data collection and analysis Arterial central venous and left ventricular pressures and ECG (Lead II) were continuously recorded on a Hewlett/Packard model 7788A recorder with appropriate amplifiers Cardiac outputs were determined in duplicate by the dye dilution technique Immediately after each cardiac output determination and microsphere injection arterial blood samples were analyzed with a Radiometer Model 27 blood gas analyzer Temperatures of the pH and blood gas electrodes were preadjusted to sampling temperature in order to eliminate temperature correction errors [5]

The distribution of blood flow was determined by left ventricular injections of Sc ^{95}Nb ^{85}Sr Cr and ^{141}Ce nuclide labeled microspheres By using one isotope at each data collection point five separate blood flow determinations were done in each animal

The radioactivity of each vial containing tissue or ash was counted using a Packard NaI Model 9011 scintillation counter energy distribution patterns were recorded on a Packard Pulse Height analyzer and the composite spectra for all five nuclides were stored on magnetic tape for processing by a PDP 15 computer

The percentage of cardiac output (%Qt) to each organ was calculated as the amount of each nuclide's radioactivity in that organ divided by the total body count for that nuclide Blood flow to each organ was calculated as percentage of cardiac output times the cardiac output from the dye-dilution determination Peripheral and organ resistances were calculated by dividing the difference between mean arterial and mean venous pressure by flow

The raw data were tabulated and processed to yield the means and standard errors of means for each parameter Statistical significance was confirmed or denied where appropriate with the Student's t test for paired or unpaired data Changes were considered significant when the value for P was less than 0 05

Results

All animals were anesthetized and cooled uneventfully with changes in hemodynamic and blood gas parameters similar to those in the previously reported series were blood flow and distribution were studied during the cooling phase [24]

Hemodynamic parameters during rewarming Hemodynamic blood gas and hematocrit data are shown in Table I Heart rate which was about 30% of unanesthetized control values in both groups at 20° C was significantly less than control until the completion of rewarming in the non arrested animals. Mean arterial pressure

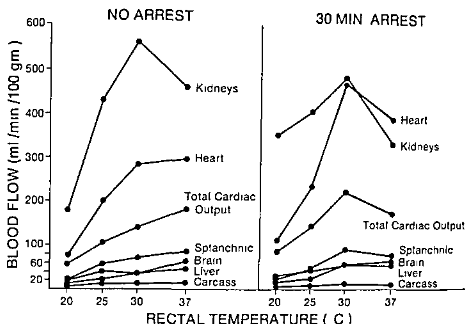

Fig 2 Absolute organ blood flows and total cardiac output during rewarming

resistance remained near 50% of control thereafter Arrested animals showed an increase to control value at 25° 30° and 37° C Arrested animals had significantly greater carcass vascular resistance from non arrested animals at 25° and 37° C

Distribution of cardiac output (Table II) In non arrested animals the %Qt distributed to the coronary circulation was decreased but insignificantly so, throughout rewarming Coronary %Qt was significantly decreased in the arrested group at 20° C but thereafter increased to levels significantly greater than in non arrested animals at the completion of rewarming (37° C)

The percentage of cardiac output distributed to the brain was significantly reduced (60% of control) at 20 C in animals not subjected to circulatory arrest Cerebral %Qt began to increase by 30° C and had returned to control at the completion of rewarming Animals subjected to arrest had a significantly greater %Qt distributed to the brain than non arrested animals at 20° and 25° C Furthermore %Qt was not significantly different from control at any time during rewarming in arrested animals

Renal %Qt was not significantly altered by rewarming in the non arrested group although absolute values tended to decrease between 30° and 37° C In the arrested group the trend was to a decreasing *renal %Qt which became significant*ly less than control value at the completion of rewarming

Hepatic %Qt tended to be greater than contr at 20° C with a decline to control by 37° C non arrested animals Arrested animals showe the opposite trend that is an initial decrease 20° C with a steady increase thereafter The trends although consistent were not statisticall significant

Splanchnic %Qt in non arrested anima increased during rewarming to significantly hig er levels at 30° and 37 C A similar trend wa observed in the arrested group

Carcass %Qt tended to decline in both group during rewarming but the differences were no significant

Changes in organ blood flow (Table II Fig 2) Coronary flow which was significantly belov control at 20° and 25° C increased with rewarm ing in the non arrested group Arrested animal tended to have greater coronary flows than non arrested animals and at 30 C the difference wa significant

Cerebral blood flow was significantly below control until rewarming was completed in th non arrested group Arrested animals showed sig nificantly reduced flow at 20 and 25° C but at 30° C the trend was toward control values at 37 C however flows had again decreased to levels significantly below control When the two groups were compared cerebral flow was twice as great *in arrested vs non arrested* animals at 20° C and at 25° C

Renal flows were subject to large individual

*The symbols for statistical analyses are described in Table I

Coronary vascular resistance in the non arrested group was at about 150% of control at 20 C during rewarming decreased rapidly to slightly below control at 25 C and decreased only slightly thereafter These changes were not statistically significant due to large individual variation In the arrested group coronary resistance was similar to control value at 20 C but was significantly reduced at 30° and 37° C

Renal vascular resistance was not significantly changed from preanesthetic control throughout rewarming in the non arrested group Arrested animals had significantly decreased renal vascular resistance at 20° C but resistance increased during rewarming to levels significantly greater than in non arrested counterparts of the completion of rewarming

Splanchnic vascular resistance was the most variable of the organ systems evaluated In both groups hepatic resistance was below control throughout rewarming

Carcass vascular resistance in the non arrested group was reduced at 20° C during rewarming The reduction was significant at 25° C and

ry reduction in flow to other organs and a previous study in dogs showed no change in blood volume at the onset of rewarming.[5] Thus it seems unlikely that the effects of surface rewarming on TVR and carcass vascular resistance at 20° C can be accounted for by major changes involving vasomotion.

The TVR in non arrested animals was similar at 25°, 30°, and 37° C during rewarming and was significantly less than the unanesthetized normothermic control value. While the influence of surface heating described above may explain generally lower resistances during rewarming than at comparable temperatures during cooling, it also suggests that TVR should change progressively with rewarming instead of remaining stable at and after 25° C. We have examined other factors that are capable of influencing TVR during rewarming. These include (1) oxygen consumption, which has been shown to be higher at comparable temperatures during rewarming[15] (2) anesthetic level, which, as judged by clinical signs is the sum of the effects of anesthetic concentration and cold depression (circulatory arrest may also exert a depressive effect since arrested animals usually require less anesthetic during rewarming) (3) cardiac output, which progressively rises during rewarming but was greater at 20° C and less at 37° C in arrested vs non arrested animals (4) blood volume, which is unchanged following rewarming in non arrested dogs but decreased in animals subjected to arrest[8] (5) plasma catecholamines, which are markedly elevated for a brief period following circulatory arrest at 20° C but are unchanged in non arrested dogs.[16] While the interaction of these factors is not entirely understood, it is clear that TVR differences during rewarming vs cooling and between the arrested and non arrested groups in this study involve varying degrees of functional autoregulation at deep hypothermic levels.

Blood flow in individual organs. Assessing the adequacy of blood flow to the brain is difficult since it shows little correlation with functional and histopathological changes.[17, 22] In addition the level of cerebral blood flow necessary to maintain basal c nditions may be considerably below the level necessary to provide maximal tissue reserves and e the maximum possible safe circulatory o n time at a given temperature. Recent stud Ohmura and associates[18] and by Hagerdal and colleagues[5, 6] give credence to the concept that the integrity of the brain can probably only be accurately monitored on the metabolic or biochemical level. Until better monitoring methods are established, however, an interim approach involves comparing cooling and rewarming cerebral flows in arrested and non arrested animals. Using our technique of deep hypothermia,[13] we have maintained surface cooled dogs at temperatures below 20° C for up to two hours following surface rewarming; no change—including such judgmental factors such as appetite, degree of activity, etc.—could be detected. Half term puppies cooled in utero and not arrested in mothers who were arrested for one hour have come to normal delivery,[12] grown to adulthood and been cooled again and arrested for one hour and have not suffered detectable changes (unpublished data). These observations and other studies of cerebral oxygen consumption and metabolism[5, 18] leave little doubt that cerebral blood flow during cooling is adequate with the method described herein.

During rewarming absolute cerebral blood flow was always greater than at equivalent cooling temperatures. Furthermore, the cerebral %Qt, absolute flow, and cerebral vascular resistance data confirm a reactive hyperemia following resuscitation and rewarming in arrested animals that did not occur in non arrested animals.

In both groups of animals during rewarming, coronary blood flow was consistently maintained at higher values than at comparable temperatures during cooling. These flows occurred despite differences in cardiac output and coronary vascular resistance, strongly suggesting intact autoregulative function. Under normothermic basal conditions coronary venous oxygen content is very low so that an increased oxygen demand must be supplied by an increase of coronary blood flow. Similarly, coronary blood flow must increase to compensate for decreased oxygen supply due to reduced oxygen content or other causes such as a shift in the oxyhemoglobin dissociation curve. During hypothermia the interaction of these factors may be complex; however, the fact that myocardial oxygen requirement is determined by the amount and kind of cardiac work has yet to be disproven under conditions of hypothermia. At normothermia, cardiac indices have been developed which relate cardiac work to oxygen consumption and hence to coronary flow. Such rela

variations in both groups It was apparent however that renal flow in both groups increased during rewarming from 20 to 30° C and then decreased with further warming to 37° C Furthermore arrested animals had significantly greater flows at 20° C than did non arrested animals

Hepatic arterial flow in the non arrested group was approximately 30% of control at 20° C and increased with temperature to near control by 37° C These changes were not statistically significant due to individual variations during the pre anesthetic control determinations Arrested animals had significantly reduced hepatic flows at 20 and at 25° C with an increase toward control by 37 C

Splanchnic blood flow increased throughout rewarming in both groups and was significantly greater than control in non arrested animals at 30 and at 37° C

Carcass flows in both groups were significantly reduced from control values at 20 C At 37° C carcass flow in arrested animals was still significantly reduced whereas it had returned to control in non arrested animals

Discussion

Our previous report[2] discussed the effects of surface cooling and ether anesthesia on regional blood flow It was also noted that only about five separate microsphere injections are practical on this basis we elected to study the cooling and rewarming phrases of deep surface hypothermia separately While this approach comprises statistical comparisons between the cooling and rewarming phases it has the advantage of doubling the number of observations over the whole procedure

The present study reveals that rewarming is a complex process with vascular resistance output fraction to various organs and organ blood flow varying in response to both rewarming and circulatory arrest At 20° C shortly after the initiation of surface rewarming the TVR in both arrested and non arrested animals decreased abruptly to approximately 50% of the levels seen at 20° C during cooling As rewarming continued the TVR of non arrested animals stabilized at levels significantly below the awake control whereas arrested animals showed fluctuating generally higher TVR (Table I) Since cardiac output is only slightly (and insignificantly) greater in the arrested group at 20° C it seems likely that rewarming *per se* exerts the dominant influence during the first few minutes of surface rewarming In dogs cooled by ice-water immersion subcutaneous temperatures quickly fall to 10 C or less and skeletal (thigh) muscle also cools rapidly the latter usually reaching 15° C while the core (brain liver rectal) temperature is at 20 C (unpublished data) During rewarming in a 40 C bath skin and skeletal muscle temperatures are normothermic or nearly so by the time core temperature has reached 25° C The fact that whole body vascular resistance and carcass vascualr resistance change in a parallel fashion at the initiation of rewarming again strongly suggests the dominant role of surface heating as a cause of the abrupt reduction of TVR

There is considerable evidence that the above changes with the induction of surface rewarming are not entirely the direct vasodilatative effect of heat Several studies have shown that both cooling[1] [?] and ether anesthesia can result in maximal peripheral capillary and arteriolar dilatation in which case significant cutaneous or skeletal muscular vascular dilatation should not occur with the induction of surface rewarming Furthermore the relationships between temperature and blood viscosity have been well documented [9] and it has been observed that blood viscosity rises rapidly with a decrease in temperature below 27° C [9] [3] As surface cooling is started skin temperature decreases rapidly to near 0° C while the core is still normothermic creating a temperature and temperature-induced viscosity gradient in the central vs the peripheral vascular compartment Surface rewarming quickly reverses this gradient thus the immediate decrease in skin and skeletal muscle vascular resistance noted in this study at the onset of surface rewarming may be the result of reducing blood viscosity in the vessels closest to the surface This effect would potentially improve venous return to the heart and tend to explain (1) why cardiac output is greater at 20° C during rewarming than at 20° C during cooling and (2) why cardiac output begins to increase during surface rewarming before a detectable increase in core temperature is evident

Carcass vascular resistance is halved by the initiation of surface rewarming at 20° C If this is the result of vascular dilatation then intravascular volume would increase accordingly or be compensated for by a decrease in the volume (vasoconstriction) in other organ systems The current study shows that there is no compensato

ng rewarming especially in arrested animals CO ippeared to be similar to those noted at compar ible cooling temperatures until 30° C during 'ewarming thereafter CO did not fully recover to iwake control levels These data suggest that 'egional flow is redistributed from the carcass and 'enal circulations to cerebral and coronary circu ations in response to hemodynamic alterations luring surface rewarming It was concluded that iutoregulative responses to both circulatory irrest and hemodynamic factors are elicited dur ng surface rewarming from deep hypothermia to !0° C with the method described

We would like to thank Mr Clifford Pitts and Mr Lewis 'urcell for their excellent assistance

tionships have not been well established during hypothermia so that changes in coronary flow with various cooling methods have resulted in much conjecture Studies by others have shown that coronary flow and coronary resistance may increase or decrease depending upon temperature and the method of cooling [6, 2, 26] We suggest however that there is no reason to believe that the principles of normothermic coronary autoregulation (primarily oxygen demand) do not function within the temperature range than can be achieved with surface cooling (18° to 20 C) It also seems likely that a better understanding of the determinants of myocardial oxygen demand during hypothermia would resolve many of the apparent discrepancies regarding coronary flow reported in the literature

The present study revealed coronary vascular resistance and flow patterns consistent with a hyperemic response following circulatory arrest that was not evident in non arrested animals In previous studies using dogs under similar conditions we found that plasma catecholamines are elevated immediately following circulatory arrest[1] and that coronary A V lactate balance became negative These data support the conclusion that the coronary circulation does respond to metabolic stimuli even at 20° C

Our data suggested that renal blood flow during cooling paralleled the decline in cardiac output since the renal %Qt was unchanged During rewarming the significantly greater absolute renal flow in arrested animals at 20 C as compared to immediately rewarmed animals probably represents a hyperemia As rewarming progressed the renal %Qt decreased especially in arrested animals so that absolute flow was below control values at 37° C The cause of these reduced flows is explained by the slightly reduced cardiac output[15, 7] and blood and plasma volumes that are known to occur following rewarming with this hypothermia method The absence of primary post rewarming renal failure and histopathologic changes in dogs subjected to a similar protocol is consistent with the hypothesis that the transient shift of flow away from the kidneys is related to cardiovascular dynamics and blood volume rather than to low temperature *per se* In fact Tempel and associates [5] have shown that changes in these parameters are sufficient to explain decreased renal function at low temperatures during both induced hypothermia and normal hibernation

From a practical clinical standpoint such considerations imply that the cardiovascular and/or blood volume status rather than primary kidney alterations should be suspected as the cause of renal malfunction in the post hypothermic patient with poor urine output Additional studies should be done to confirm and expand these relationships and their validity in the patient with congenital cardiac disease following repair under deep hypothermia

Interpretation of liver and splanchnic flow data was hampered by large individual variations While in part related to methodology the greater variance in these systems might be expected because they play a major role in terms of immediate circulating volume adjustments Morphologic studies in dogs revealed some dilatation of hepatic sinusoids after cooling to 18 C [6] and we have recently shown that the hepatic sinusoids are the site of the platelet sequestration phenomenon associated with surface cooling [9]

This study demonstrates that the regional distribution of blood flow is not necessarily similar at specific temperatures depending (1) upon the stage of the procedure (cooling as opposed to rewarming) and (2) upon the addition of a period of circulatory arrest prior to rewarming This knowledge and the microsphere technology if expanded will likely provide a basis for comparing hypothermia techniques especially if low temepratury regional flow requirements can be ascertained and correlated to functional and histopathologic changes following rewarming

Summary

Regional blood flow and distribution of cardiac output (CO) were evaluated by the radioactive microsphere technique in rhesus monkeys during surface rewarming following the induction of deep hypothermia (20° C) under deep ether anesthesia A comparison of animals subjected to 30 minutes of circulatory arrest and those not arrested revealed cerebral coronary and renal vascular resistance and flow patterns consistent with a hyperemic response to circulatory arrest at 20° C Throughout rewarming cerebral and coronary absolute flows tended to be at or above the flows noted at comparable cooling temperatures in a previous study Renal flow fraction (% Qt) were well preserved during rewarming to 30° C but a decrease was observed thereafter Carcass (muscle skin bone) %Qt was also reduced follow

of quinidine base was injected intravenously over a period of one minute Samples of blood (4 to 5 ml) and CSF (1 to 2 ml) were simultaneously taken before the infusion and at the following post infusion times 5 10 15 30 and 45 minutes 1 1 5 2 2 5 3 3 5 and 4 hours then hourly for up to 8 hours after the dose Serum and CSF were stored at –20° C until the time of assay

After an interval of two weeks serum quinidine kinetics were studied again without anesthesia in two of the four dogs to assess the effect of the anesthetic procedure CSF was not sampled

In vitro study The partitioning of quinidine between wat r and n octanol at physiologic pH was determi d in vitro A solution of quinidine sulfate (5 μg [illegible]) in phosphate buffer (pH 7 4) was shaken w [illegible] equal volume of octanol The quinidine conc [illegible] ion in the aqueous phase was determined be [illegible] d after the octanol extraction

Analysis of sa [illegible] s Quinidine concentrations in all samples (se [illegible] CSF or phosphate buffer) were determined by modification of the double extraction spectrophotofluorometric technique The extent of quinidine protein binding in each serum sample was determined by equilibrium dialysis [9]

Results

Percent unbound quinidine in serum among the eight human subjects ranged from 13 1 to 22 2% (Table I) CSF concentrations were always lower than unbound serum levels at the time of sampling The mean (± SE) CSF to unbound serum concentration ratio was 0 16 (±0 03) with a range of 0 04 to 0 37

The mean percent unbound serum quinidine among the four dogs ranged form 7 9 to 18 8% (Table II) However percent unbound serum quinidine increased with increasing total quinidine concentrations (Table II Fig 1) consistent with concentration dependent protein binding

Quinidine appeared promptly in CSF of all four dogs (Fig 2) Quinidine concentrations in serum

Entry of quinidine into cerebrospinal fluid

Central nervous system (CNS) toxicity is commonly associated with the use of quinidine derivatives in clinical practice [1-4] The characteristic syndrome of mild cinchonism includes headache tinnitus and blurring of vision More severe cinchonism can include marked auditory and visual disturbances as well as behavioral and neurologic disorders [5,6] Gastrointestinal toxicity attributable to quinidine (diarrhea nausea vomiting) may also refect effects on the CNS inasmuch as these symptoms can be caused by parenteral administration of quinidine [7] Furthermore quinidine can produce emetic movements in eviscerated animals [8]

Despite the clinical importance of quinidine s central toxicity few data are available on the rate and extent of its entry into the CNS The present study assessed simultaneous serum and cerebrospinal fluid concentrations of quinidine in a series of human subjects We also studied the rate and extent of quinidine entry into cerebrospinal fluid in dogs

Methods

Human studies Eight volunteers scheduled for diagnostic lumbar puncture participated after giving informed consent Subjects received 500 mg of quinidine bisulfate at 12 hours and again at 2 hours prior to the procedure A sample of venous blood together with a 1 to 2 ml aliquot of cerebrospinal fluid (CSF) were obtained simultaneously Blood samples were allowed to clot at room temperature then were centrifuged Serum and CSF were stored at −20 C until the time of assay

Animal studies Four adult mongrel dogs (20 to 32 kilograms) were anesthetized with intravenous pentobarbital (30 mg /kg) intubated and ventilated with a Harvard respirator to maintain arterial oxygen tension within normal limits Body temperature was maintained with a heating pad and fluid losses were approximately replaced with intravenous 0.9% sodium chloride solution A 7 5 cm spinal needle (19 gauge) was inserted into the cisternum magnum to allow repeated sampling of CSF

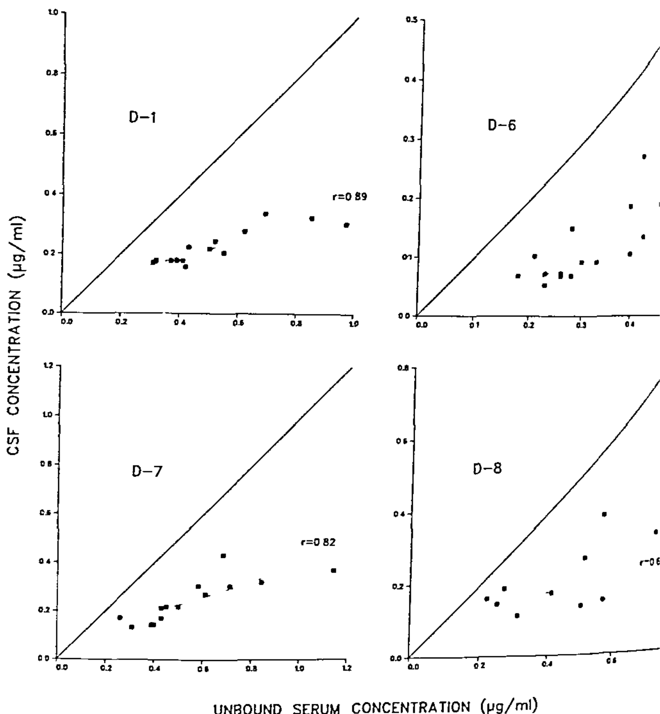

Fig 3 Simultaneous unbound serum and CSF concentrations of quinidine in four animals *Solid diagnonal lines* are the theoretical functions of identity (unbound serum = CSF concentration) Actual data points always fall below the line (unbound serum greater than CSF concentration) *Dashed lines* were determined by least-squares regression analysis.

CSF concentrations were considerably lower than unbound serum concentrations in each of the human subje t studied The findings were con firmed when the rate and extent of quinidine entry into (SF was studied in dogs The results of the animal dies are not likely to reflect non equilibrium ditions due to slow entry of quin idine into CSF In fact quinidine appeared ve rapidly in dog CSF following which CSF a unbound serum concentrations declined in para lel with a nearly constant ratio maintai between the two This strongly suggests th distribution equilibrium was rapidly attained In the human studies, the clinical con trai

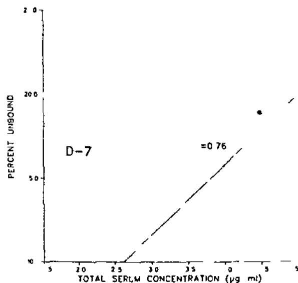

Fig 1 Relation of the extent of quinidine protein binding to total serum quinidine concentration in Dog No 7 Note that binding decreases with increasing total serum concentration (r = 0 6 p < 0 01)

(unbound and total) and in CSF declined in parallel CSF quinidine concentrations were always less than unbound serum levels (Figs 2 and 3) although the two were highly correlated in all four animals The mean ratio of CSF to unbound serum quinidine ranged from 0 37 to 0 45 among the four dogs (Table II)

The elimination half life of quinidine in the two animals studied both without and with barbiturate anesthesia was prolonged by anesthesia from 3 7 to 16.2 hours and from 5.3 to 12 3 hours respectively (Fig 4) Total quinidine clearance was correspondingly reduced during anesthesia The findings suggest that some aspect of the general anesthetic procedure is associated with marked impairment of quinidine clearance

The ratio of quinidine concentrations measured in the aqueous phase before and after mixing with octanol was 133 indicating greater than 99% partitioning into octanol at physiologic pH

Discussion

Physicochemical factors influencing the passage of drugs and plasma constituents from blood to CSF are known to include the degree of drug binding to plasma protein the degree of ionization at physiologic pH and the lipophilicity of the undissociated molecule Many drugs are moderately lipophilic when undissociated and at physiologic pH are at least partly undissociated

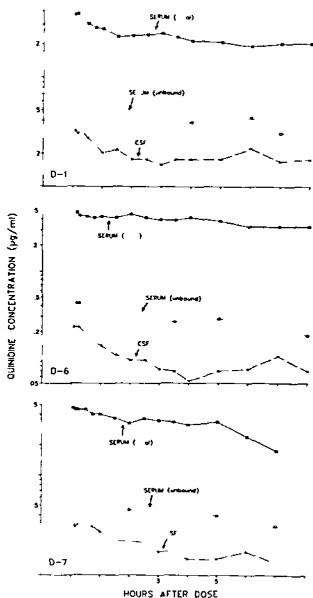

Fig 2 Concentrations of quinidine in serum (unbound and total) and in CSF following intravenous quinidine (10 mg /kg of quinidine base) administered at time zero to three representative dogs

If the passage of such compounds into CSF occurs by passive diffusion then CSF concentrations after attainment of distribution equilibrium are approximately equal to the unbound concentration in plasma[15] In the case of quinidine a weak organic base its octanol water partition characteristics suggest that the fraction of total drug existing as the lipophilic free base at physiologic pH is sufficient to favor rapid equilibration of unbound serum quinidine with CSF if passive diffusion alone governed the process[17] However

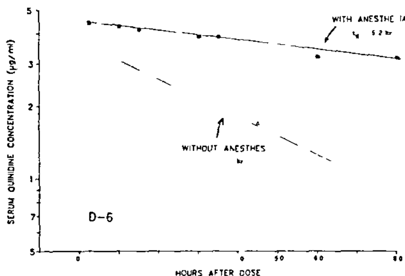

Fig 4 Total serum quinidine concentrations in Dog No 6 after intravenous injection of quinidine (10 mg/kg of quinidine base) on two occasions, with and without concurrent general anesthesia The elimination half life ($t_{½}$) was more than four times longer when quinidine was given during general anesthesia

requiring lumbar CSF sampling might lead to lower CSF quinidine concentrations than those present at sampling sites closer to the brain due to the time required for circulation of CSF [9] However this is unlikely to account for the large differences between unbound serum and CSF quinidine concentrations The findings therefore suggest that passage of quinidine into CSF is not determined simply by passive diffusion It may be that quinidine participates in an active transport such as that known to remove from CSF other basic substances including morphine codeine atropine and gentamicin [33]

Total quinidine clearance in the dog studies was markedly lower in the anesthetized state when compared to values measured upon retesting in the unanesthetized condition This could be explained either by a direct inhibitory effect of pentobarbital upon hepatic biotransformation of quinidine or by hemodynamic changes associated with the anesthetized condition In any case it is clear that kinetic properties of drugs established in studies of conscious animals or humans are not necessarily applicable during general anesthesia

Summary

Some of the unwanted effects of quinidine commonly occurring in clinical practice involve the central nervous system We therefore assessed the rate and extent of quinidine passage into cerebrospinal fluid (CSF) in humans and dogs In eight human subjects receiving oral quinidine therapy lumbar CSF quinidine concentrations averaged 16% of unbound serum concentrations (range 4% to 37%) The findings were confirmed when simultaneous serum (total and unbound) and CSF quinidine concentrations were followed for up to 8 hours after a single intravenous dose of quinidine in anesthetized dogs Quinidine appeared promptly in CSF of all animals, but CSF concentrations averaged only 37% to 46% of unbound serum levels The in vitro octanol water partition coefficient for quinidine at physiologic pH was greater than 100 indicating that unbound quinidine should readily traverse the blood brain barrier Thus passage of quinidine into CSF appears not to be governed by passive diffusion alone Quinidine may participate in an active transport system such as that which removes certain other basic substances from CSF

in a chronic alcoholic patient coincidental with a serum aprindine level of 3 μg/ml In another study, those patients developing psychosis while on aprindine had previous histories of mental illness or hypoxic brain damage[3] Other authors feel that the neurologic side effects of aprindine generally did not occur at serum levels less than 1 μg/ml without fine tremor and dizziness occurring prior to intention tremor ataxia and the other CNS manifestations[5] Here, patients reporting hallucinations had serum levels of 1 6 to 3 6 μg/ml

Our patient had no psychiatric history and on previous hospitalization both in the CCU and on the floors had never exhibited any signs of depression or bizarre behavior The sudden onset of psychosis concurrent with aprindine administration and its subsequent complete resolution after discontinuing the drug is strong evidence of drug induced psychosis The serum level of 1 05 μg/ml is only borderline therapeutic and does not approach the levels previously reported in patients with psychosis while on aprindine In addition she did not exhibit any other CNS side *effects associated with aprindine toxicity* We conclude that psychosis may appear as an isolated side effect of aprindine administration at relatively low serum levels The drug s efficacy in suppressing ventricular arrhythmias, especially in patients with the mitral valve prolapse syndrome, is reinforced It remains however an agent with significant side effects that restricts its use to patients in whom other anti arrhythmic therapy has been unsuccessful

Summary

A young woman with mitral valve prolapse and ventricular tachycardia refractory to numerous antiarrhythmics received a trial of aprindine During the course of treatment she developed a severe psychotic reaction that resolved after the drug was stopped Her psychosis was unassociated with the other dose related neurological side effects of aprindine and occurred at borderline therapeutic levels of the drug

We wish to thank Dr Thomas Rommer for referring this patient to us for the therapeutic trial

Case reports

Aprindine psychosis

Glenn P Jacobs M D
Ira H Pores M D
Newark N J

Aprindine is an anti arrhythmic drug presently being used in clinical investigation for the treatment of refractory supraventricular and ventricular tachycardia The various side effects reported including agranulocytosis cholestatic hepatitis and neurological reactions such as tremor and ataxia are dose related and reversible We report here a case of acute psychosis developing at borderline low therapeutic levels of aprindine

Case report

The patient is a 29 year-old female who was in previous good health and who six months prior to thi admission developed coughing and wheezing while at work She was examined by a physician who discovered an irregular pulse and admitted her to the hospital for further ork up Initial ECG revealed frequent PVC s with coupling and the patient was admitted to the CCU for observation Evaluation by echocardiogram at that time disclosed the presence of mitral valve prolapse The electrocardiogram showed frequent I VC s and non specific ST T wave changes in Leads II III and aV with normal QT interval CBC electrolytes BUN glucose calcium magnesium cardiac enzymes arterial blood gases and ventilation-perfusion lung scan were all normal. Holter monitoring revealed frequent PVCs bigeminy trigeminy couplets and several runs of ventricular tachycardia lasting as long as 12 to 15 seconds. For control of palpitations and the arrhythmia multiple combinations of Inderal (propranolol HCl) Norpace (disopyramide) dilantin and quinidine were used. The patient was discharged on Norpace 300 mg orally every 6 hours and Inderal 100 mg orally every 6 hours.

During the ensuing 5 months she was followed as an outpatient Because of persistent ventricular tachycardia and complaints of palpitations she was readmitted to the Newark Beth Israel Medical Center for a trial of aprindine She was taking digoxin 0 25 mg daily propranolol HCl 40 mg every 6 hours and quinidine gluconate 1 tablet every 8 hours

She had not been on any other medications except for oral contraceptives which were stopped 5 months prior to admission She is the working mother of three children with no history of depression or psychosis She neither smoked nor used alcohol

Physical examination revealed a young female in no distress with an irregular pulse of 76/minute Lungs were clear Examination of the heart disclosed a non-ejection click, with a late systolic murmur on standing The remainder of the examination was unremarkable

All medication was stopped for 24 hours and the patient was placed in the CCU After baseline CBC electrolytes bilirubin SGOT SGPT alkaline phosphatate and T were obtained aprindine was started orally On day one 300 mg was given in three doses on day two 150 mg was given in two doses on day three 200 mg. was given in two doses From the fourth day she was maintained on aprindine 75 mg orally twice a day A marked therapeutic response was noted with only single PVCs on her Holter monitor tracings

On the sixth day of therapy she became extremely agitated anxious and combative She had delusions of having died in her sleep and thought she was being poisoned throu h the air conditioning At this time her physical examination was unchanged She had no tremor ataxia or nystagmus

She was seen in psychiatric consultation and was felt to be having an acute psychotic reaction possibly on a toxic basis. Her serum chemistries CBC liver and cardiac enzymes were all within normal limits An aprindine level drawn at that time was 1 05 μg/ml. (Eli Lilly Laboratories) The aprindine was withheld and over the next 3 days her mental status returned to normal

Discussion

Previous reports of hallucinations and psychosis during aprindine therapy were in patients in whom either toxic serum levels were achieved with accompanying tremor ataxia or nystagmus or in clinical situations where the etiology of the psychosis was impossible to ascertain [1] Hagemeijer and colleagues [2] in their clinical studies of aprindine in patients with acute myocardial infarctions found three patients with disorientation hallucinations and nightmares Aprindine levels were measured in two of these and were greater than 3 μg/ml Delirium tremens appeared

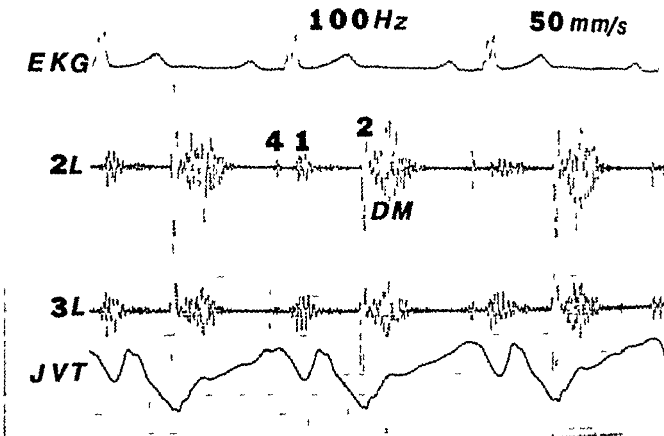

Fig 1 Phonocardiogram showing a fourth heart sound and a diastolic murmur following the pulmonic component of the second sound. JVT = jugular venous tracing

ventricle was dilated Cardiac catheterization data appear in Table I The pressure contour in the pulmonary artery was strikingly similar to that of the right ventricle consistent with severe pulmonic regurgitation Injection of contrast material in the pulmonary artery demonstrated 4 plus pulmonic regurgitation Selective injection of both the right ventricle and pulmonary artery demonstrated a 2 by 3 cm accumulation of dye in the right ventricular outflow tract which was best seen in diastole (Fig 4) The contrast material appeared to be trapped within a structure or mass A small but prominent calcification was noted adjacent to this accumulation of contrast material A tumor was judged to be present together with severe pulmonary regurgitation and surgical intervention was recommended

Significant dilatation of the pulmonary artery and right ventricular outflow tract was noted at surgery Following right ventricul ot my n tumor was found There was a small 5 mm in diam et r calcified polyp like mass on the septal side of the right ventricular outflow tract (Fig 5A) Pulmonary arteriotom r led a tricuspid pulmonic valve with the left leaflet inta t The remaining leaflets had large fenestrations occupying ximately 60% of their area (Fig 5B) The valve tissue thin and glistening The margins of the fenestrations wer h with normal endothelialization and without evidence n r previous infection Primary closure of each fen wa accomplished The postoperative course was ur All blood cultures before and at the time of surgery growth

Postoperatively the patient had a grade I/VI systo ejection murmur and a grade II/VI harsh diastolic murm along the left sternal border Neither M mode echocardiogra (Fig 2B) nor 2 D echo revealed any mass or abnorm reflectance in the right ventricular outflow tract Repe cardiac catheterization (Table I) revealed normal pulmona arterial pressure contours and 2 plus pulmonic regurgita No abnormal accumulation of contrast material occurred the right ventricular outflow tract

The patient is currently nine months postoperative an functions at full activity but continues to have physi findings of mild pulmonic regurgitation

Discussion

M mode and more recently two dimensional echocardiography have assumed paramount importance in the evaluation of intracardiac tumors The accuracy of these techniques to diagnose primary cardiac tumors as well as extra cardiac tumors is impressive Occasional reports exist in which other structures including mitral stenosis nonthrombotic masses on the mitral valve mitral valve prolapse and ventricular pacemaker wires can mimic intracardiac tumors

In recent years M mode and two dimensional echocardiography have greatly enhanced our ability to recognize intracardiac tumors noninvasively [1-4] However the limitations as well as the usefulness of this technology warrant emphasis

Case report

This asymptomatic 26-year-old man was referred for evaluation of a heart murmur There was no history suggestive of infective endocarditis scarlet fever rheumatic fever or drug abuse Cardiac murmurs which were thought to be systolic were heard at 12 and 18 years of age

Physical examination revealed a blood pressure of 120/80/75 mm Hg The neck veins were flat at 45 degrees incline with a dominant "a" wave Carotid and peripheral pulses were full and equal and there was no evidence of cyanosis clubbing or edema The chest was clear The point of maximum impulse was in the fifth left intercostal space at the mid clavicular line The first heart sound was of normal loudness as was the second heart sound which demonstrated physiologic splitting No ejection clicks were present A fourth heart sound was best heard along the lower left sternal border There was a short high frequency mid systolic murmur and a harsh middle frequency grade III/VI diastolic murmur along the left sternal border (Fig 1) Both murmurs increased with inspiration

The chest x ray was normal The electrocardiogram demonstrated a vertical axis and was within normal limits. The M mode echocardiogram demonstrated dense echoes posterior to the pulmonic valve during diastole consistent with a right ventricular outflow tumor (Fig 2A) Other sections of the M mode echocardiogram failed to demonstrate right ventricular enlargement paradoxical septal motion or fluttering of the anterior leaflet of the tricuspid valve Wide angle two-dimensional (2 D) echocardiography (Fig 3) revealed a prominent reflectance in the right ventricular outflow tract which measured approximately 2 by 2 cm. in diameter and imaged only during diastole The motion of the structure was that of the surrounding right ventricular outflow tract The bright reflectance or "mass-like" structure was always below the pulmonary valve and demonstrated no apparent involvement of either the valve or pulmonary artery The real time 2 D echo images of the pulmonary valve were normal. In contrast to the appearance of the M mode echocardiogram the right

Table I Pre operative (column A) and postoperative (column B) cardiac catheterization findings

	A		B

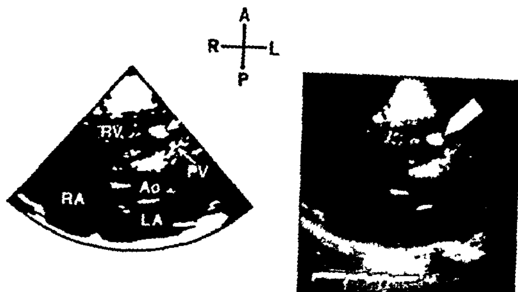

Fig 3 Two-dimensional echocardiogram of right ventricular *(RV)* outflow tract revealing dense echoes in RV outflow tract beneath the pulmonic valve *(arrow)* *RA* = right atrium *Ao* = aorta *LA* = left atrium *PV* = pulmonic valve *A* = anterior *P* = posterior *R* = right *L* = left

In retrospect the dense reflectances observed on both M mode and 2 D echo studies in the right ventricular outflow tract during diastole were generated by the 5 mm calcified polyp like mass This small lump which contained no tumor cells was thought to be consistent with a jet lesion secondary to the long standing congenital pulmonary insufficiency Because of its small size and the normal motion of the contracting right ventricle the calcium moved out of the path of the echo beam during systole

Because of beam width resolution error the mass like reflectance on M mode echo appeared to be involving or much closer to the pulmonic valve compared to what was actually found Motion and thickness of pulmonic valve leaflets were confirmed to be normal with 2 D echo and the structure in question did not involve or attach to the valve In retrospect the obvious site of calcification on fluoroscopy should have alerted the echocardiographer that the apparent mass on 2 D imaging may have been generated by the calcium

The echocardiographic interpretation error was compounded by the localized accumulation of contrast material on the angiogram in the same region of the right ventricular outflow tract This localized trapp[illegible] dye was thought to be related to [illegible] p[illegible] of mass whereas in retrospect it was [illegible] an unusual accumulation of dye amid [illegible] trabeculations of the dilated

Fig 4 Angiography of the right ventricular outflow tract seen from a lateral view demonstrating an oval accumulation of contrast material *(arrow)* beneath the pulmonary valve

outflow tract fortuitously directed by the two large fenestrations in the pulmonic leaflets There was no relationship between the small calcified lesion and the nearby accumulation of contrast material

In the absence of any other abnormality involving the pulmonic valve it is not surpris[illegible] that both M mode and 2 D echo studies revealed the valve to appear normal Echocardiography is quite insensitive to identify isolated pulmonary valve insufficiency

Isolated congenital pulmonic valvular regurgitation is a rare anomaly more frequently congen[illegible]

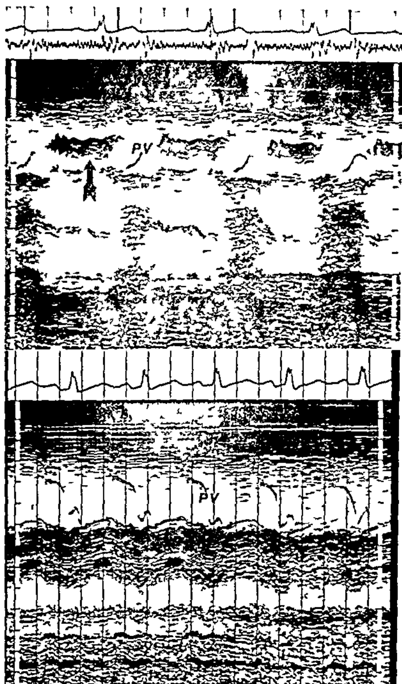

Fig 2 *A (top panel)* M mode echocardiogram of pulmonic valve showing dense echoes beneath the pulmonic valve *(PV)* during diastole *(arrow)* *B (bottom panel)* M mode echocardiogram of pulmonic valve *(PV)* postoperatively demonstrating absence of dense reflectances beneath pulmonic valve seen preoperatively The A wave amplitude is prominent

The technical problems created by side lobe artifacts of 2 D echo images and beam width resolution errors of M mode studies are well recognized It is also well known that prosthetic materials wires catheters and calcium will generate very prominent reflectances when the beam intersects them Accordingly the gain settings of the equipment must be reduced to prevent the respective structure or calcium from appearing much larger than actual size

Fig 5 *A* Small calcified mass *(arrow)* found at surgery on the septal side of the right ventricular outflow tract *B* Pulmonary valve at time of surgery demonstrating large fenestrations in pulmonary valve leaflets with normal surrounding valve tissue

ital pulmonic regurgitation is associated with a ventricular septal defect with or without pulmonic stenosis[11] The large fenestrations causing pulmonic regurgitation in our case have not been reported previously Fenestrations are usually seen as oval defects 0 1 to 0 3 mm in diameter and are of no hemodynamic importance[1] Common causes of congenital pulmonic regurgitation include bicuspid valve[1] supernumerary valves[11] and agenesis of the valve[1] The findings at surgery excluded infective endocarditis as the cause of pulmonic regurgitation in our patient Isolated congenital pulmonic regurgitation of a mild degree as presently found in our patient is associated with a very favorable prognosis

Summary

The M mode and 2 D echocardiographic features of an unusual case of a pseudo tumor of the right ventricular outflow tract are reported The unique pathologic findings of the pulmonary valve with congenital fenestrations and the clinical implications of this pseudo tumor are discussed Whenever calcification is noted at fluoroscopy to exist in a region or structure being evaluated by echocardiography caution must be taken to avoid overestimating the size Indistinct dense reflectances without specific motion or appearance of a mass further helps to distinguish the reflectances from an actual structure of significance Furthermore all clinical angiographic and echocardiographic information must be interpreted together when either the angiogram or the echocardiogram is confusing and potentially misleading

their action as being anti infarct by an analogy with the term anti arrhythmic

Definitions Myocardial Infarction and Infarct Size

Infarct size is difficult to define because both infarct and size are not necessarily clear entities The history of the use of the term myocardial infarct has been traced by Wartman[10], it was first used in 1689 to indicate a vessel stuffed in —i e occluded Later the association of regional tissue necrosis and vascular occlusion came to be called infarction i e massive regional necrosis caused by obstructive arteriosclerosis [10] Histologically there was a coagulation necrosis But room was also left for the occurrence of noncoronary necrosis [10]

Subsequently the tight association between an occlusive lesion and regional necrosis has become controversial Thus some evidence shows that (1) histologic features of coagulation necrosis can occur without associated acute occlusion especially but not exclusively in smaller infarcts or subendocardial lesions[11 12] and that (2) in addition to coagulation necrosis other types of necrosis can be recognized in particular contraction band formation or myocytolysis [13] which occurs around the border of human infarcts[1] and may be due to catecholamine induced hypercontraction of the cell [14] Other authors hold that the causative thrombus can regularly be found if searched for with sufficient care and vigor [15 17] Thus the relation between the thrombus and the histological lesion is by no means settled [18] One recent authoritative view is that the thrombus although found in just over half (60%) of the patients dying with acute transmural infarction is usually *absent in patients dying soon after the onset of* symptoms [19] Thus (1) myocardial infarction need not necessarily be associated with a vascular occlusion lesion nor need the histological damage be limited to the classical coagulation necrosis and (2) the term infarct therefore touches on certain very controversial vascular and histologic definitions

Nor is the use of the term infarct size any less free from problems of definition In the strict sense the volume of infarcted tissue should be expressed as a percentage of the total but experimental studies have generally used indirect indices such as the number of sites with electrocardiographic evidence of ischemia (ST elevation) or the degree of enzyme (creatine kinase) depletion, and only seldom has true pathological size been quantified Pathological quantification is made more difficult by the heterogeneity of the lesion with an admixture of living and dead cells [10] Quantification is more easy using the degree of myocardial depletion of creatine kinase which has however, been linked only to the severity of coagulation necrosis [1] while the relation if any, to myocytolysis (hypercontracted dead cells) remains to be determined It should also be noted that the size of the infarct assessed 24 hours post ligation is not necessarily the same as that of the eventual scar (scar size) Finally even if there were well defined pathologically uniform lesions infarct size could never be directly measured in patients except in those who died

However a number of indirect indices of infarct size have been proposed for use in patients The evaluation of *ST changes* from multiple leads as a blanket [0] or a computerized combined signal only indicates trends in the development of ischemia not infarct size [3] and is open to a *multitude of theoretical objections* [2] as well as not correlating with infarct size measured by enzyme release [3] The critical importance of distinction between an effect on ischemia and on infarct size is shown by the experience with mannitol which reduced ischemia and even features of histological necrosis after 40 minutes occlusion of the coronary artery but which had no effect when given during prolonged coronary occlusion [4]

Evaluation of *precordial Q waves* has been proposed by Hillis and associates [5] and by Selwyn and Shillingford [6 6] In patients past the acute stage of myocardial infarction the number of abnormal Q waves on a 35 lead precordial blanket could accurately predict the extent of left ventricular dysfunction as shown by cardiac catheterization and angiography [7] Askanazi and colleagues found that the extent of early ST elevation can predict the severity of subsequent Q wave formation as judged by the extent of R wave loss Their studies were carried out with conventional ECG leads and appear to hold promise for a simple method of assessing the effects of anti infarct agents which should decrease the eventual rate of Q formation for a given degree of early ST elevation

The rate of release of the enzyme creatine

Review

Myocardial infarct size Part I Basic considerations

Lionel H Opie M D
Cape Town South Africa

The concept of infarct size has been introduced into general medical management by the studies of Braunwald Maroko and their associates Reduction of infarct size and protection of the ischemic myocardium have become household terms in the vocabulary of most practicing cardiologists in the United States[3] The concept of modification of infarct size rests in part on three important observations showing that the full development of the infarct process may be measured in hours and days rather than in minutes and seconds First full development of the complete pathological process in animals may require several days Secondly experimentally produced coronary artery thrombi grow for at least 72 hours[5] Thirdly clinical observations show that reinfarction (or extension) of infarction occurs in many patients frequently after their discharge from an intensive care unit A further complication is expansion of the infarct which occurs chiefly in large transmural and not in small subendocardial infarcts in keeping with the importance of limitation of infarct size

Although the clinical syndrome of acute myocardial infarction will be the prime object of this review it must be stressed that a *pathological* diagnosis of infarction can only be made in the presence of necrosis whereas a *clinical* diagnosis can frequently be made in the early hours when the actual necrotic process is still developing Thus a more appropriate initial clinical diagnosis would be developing or impending myocardial infarction[9] This review first considers the possible initial events in developing myocardial infarction and then the factors promoting the progression from ischemia to infarction Thereafter the effects of therapeutic agents are considered

One hypothesis is that during the process of development of infarction there is an imbalance between the myocardial oxygen supply and demand Factors increasing the oxygen demand are held to worsen the ultimate infarct size Conversely factors improving the oxygen are held to improve the ultimate infarct size But confusion arises from the delicate balance between salutary and harmful effects of the specific interventions Thus for example reduction of the oxygen demand of the heart by reduction of the afterload also reduces the coronary perfusion pressure and the latter effect may reduce the collateral blood supply to the infarcting myocardium At the same time the vast number of agents available to reduce infarct size has become bewildering to the average cardiologist and the principles of choice obscure

It could legitimately be argued that infarct size reduction in patients has no place in our present state of knowledge until the results of randomized double blind studies with long term follow up become available However considerable endeavor has been put into animal experiments to show that infarct size reduction is possible and there has been much thought and discussion about methods of indirectly assessing ischemic injury and infarct size in man The topic dominates many discussions at cardiological meetings Therefore it seems appropriate to review present knowledge of the principles involved and the chief agents being evaluated in patients Because the specific aim of those agents is the capacity of limit infarct size it seems appropriate to designate

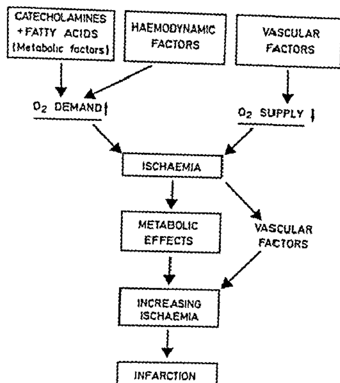

Fig 1 Ischemia can be caused by (1) a reduced oxygen supply resulting from vascular factors (see *Fig 2*) or (2) by an increased oxygen demand resulting from hemodynamic (see *Fig 3*) or metabolic factors (see *Fig 4*) Ischemia once produced can in turn produce metabolic changes that increase ischemic damage and eventually cause infarction (see *Fig 5*) Proton production may have a special role in increasing the ischemic damage (see *Fig 6*)

ischemia and those factors causing the transition from ischemia to infarction and to consider whether those processes are amenable to therapeutic intervention

Initial events in acute myocardial infarction

Animal models of myocardial infarction have generally used either (1) acute occlusion by ligature of otherwise healthy coronary arteries frequently in open chested anesthetized dogs or (2) massive injections of catecholamines The former procedure produces transmural myocardial infarction and the latter procedure produces subendocardial necrosis Even when more sophisticated techniques such as the electrical production of arterial thrombi [illegible] occlusion by a screw clamp impactor [illegible] balloon or embolization by glass balls [illegible] there are still many critical differences [illegible] the situation in patients with acute myocardial infarction

The ideal model [illegible] be a subhuman primate with spontaneously [illegible] severe coronary atherosclerosis superimposed thereon would [illegible] the primary event known to occur in man [illegible] that primary event still remains unknown [illegible] those many patients with heart attacks who [illegible] within the first hours and die an arrhythmic death[38,39] the initial event in such deaths does not appear to be an occlusive thrombus[40] except when there is bradyasystolic cardiac arrest[41] [illegible] role for evanescent thrombi or platelet aggregations[42] cannot be excluded If coronary arterial spasm should play a major or even a contributory role in heart attacks[4] then the production of [illegible] suitable animal model becomes even more complex

Nevertheless there is widespread recognition that very early lesions both in animals and [illegible] man have a variable and possibly predominant element of reversibility (ischemia) whereas the eventual lesion is irreversible (infarction) It is therefore appropriate to concentrate firstly on the factors that might produce ischemia and then on those factors underlying the transition from ischemia to infarction

Ischemia can be caused by impaired delivery of oxygen by poor blood supply as a result of *vascular factors* (Fig 1) Alternatively the oxygen demand can be enhanced by *hemodynamic* or *metabolic factors* and ischemia could result especially in the presence of some degree of reduced coronary flow Metabolic factors may also act in other ways such as promotion of membrane damage Ischemia once produced can in turn provoke metabolic and vascular changes which aggravate the ischemia and ultimately produce infarction (Fig 1) The production of ischemia by vascular hemodynamic and metabolic factors will now be considered

1 Role of vascular factors (Fig 2) Traditionally arterial obstruction has been the event initiating ischemia of sufficient severity to lead ultimately to acute myocardial infarction and mechanical block has been regarded as the most important cause of vascular obstruction [2] In addition to thrombosis arterial obstruction may be caused by embolism formation of platelet aggregates and by plaque rupture or by formation of a thrombus on a preexisting plaque[4] But the causative role of such factors especially of the thrombus is controversial Coronary vasospasm is coming to the fore not only as a cause of angina at rest but of infarction Little is known about the mechanism of arterial spasm[43] That coronary

kinase (= CK = creatine phosphokinase = CPK) has been studied extensively by Sobel's group.[29] *The theory is that the accumulation of CK in the blood derives from the infarct*, provided that no intramuscular injection has been given, in which case the cardiospecific isoenzyme MB CK should be used. In practice numerous problems arise including the high rate of enzyme destruction within the infarct zone and the difficulty of assessing the influence of factors altering the rate of removal of CK from the circulation.[1] Nevertheless infarct estimation by the CK method is a clinically useful procedure.[31] Furthermore, by making certain assumptions, the expected infarct size for any given patient can be determined from the initial CK values before the infarction and can be compared with the actual infarct size after interventions.[3] Although the latter procedure is perhaps most open to theoretical objections, nevertheless it has been used to show the beneficial effect of afterload reduction[1] and the harmful effects of digitalis given to patients without severe heart failure.[33] A practical problem with this technique is the requirement for frequent blood sampling over a prolonged period.

Radionuclide techniques are particularly popular at the moment. For example, myocardial scintigraphy with 99m technetium glucoheptonate correlates well with infarct weight in dog infarcts.[34] In patients who died with large myocardial infarction and who had been studied by 201 thallium during the acute phase, there was good correlation between scintigraphic and postmortem estimation of infarct size. But even by using a very sophisticated technique ([1]C palmitate of half life 20 minutes giving a "cold" infarct scan and quantified by positron emission transaxial tomography[1]), the results are not at present accurate enough for assessing the effects of therapy.

Thus infarct size cannot be directly measured but can only be indirectly assessed by trends in the electrocardiogram, by the patterns of enzyme release, and possibly by radionuclide techniques. Therefore, "infarct size" is not only a somewhat debatable term but is difficult to measure. The term has, however, firmly introduced itself into modern cardiological practice.

Hereafter the term "infarct size" as applied to patients will be taken to refer to such indices of infarct size rather than to accurately measured infarct size.

Differentiation between ischemia and infarction

In the original and classic paper by Maroko, Braunwald, and co-workers, the extent and severity of *epicardial ST segment elevation* 15 minutes after coronary artery ligation in the dog could be used as a predictor of the severity of myocardial cellular damage 24 hours later, as assessed either by histologic damage or by the extent of depletion of the enzyme creatine kinase (= creatine phosphokinase). It was reasoned that any increase in the degree of enzyme loss and histologic damage must indicate that the ultimate infarct was bigger and thus infarct size had increased, although the latter was never quantified in a precise pathologic sense. The Braunwald group thereafter meticulously measured both ST elevation and enzyme depletion before concluding that a variety of agents altered infarct size. Other investigators using the same model sometimes measured the ST elevation at 15 minutes and omitted the enzyme and histologic data. In patients it was a small step towards equating effects on precordial ST elevation with effects on infarct size. Although there is a relation between early ST elevation and later QRS changes, it must be understood that ST elevation is an index of acute ischemic injury provided that other causes are excluded, whereas it is the loss of R wave and formation of the Q wave that more closely corresponds to coagulation necrosis, i.e., infarction. The *difference between ischemia and infarction* is that the former is a reversible decrease in blood flow severe enough to have metabolic consequences such as depletion of ATP and anaerobic metabolism[1]—the latter is the irreversible development of tissue necrosis.

Logically, *efforts to limit infarct size in patients* would therefore be aimed at (1) countering the initial event causing ischemia and (2) countering those events causing the progression from ischemia to infarction while (3) in no way impeding the process of wound healing and scar formation. Furthermore, the effects of any such therapeutic procedure should be capable of assessment by a clinically feasible method of measuring infarct size. But infarct size cannot be assessed with complete confidence nor has its reduction yet been shown to be beneficial to the patient. Assuming that evidence will be forthcoming on the effect of limitation of infarct size in patients, it becomes logical to examine the production of

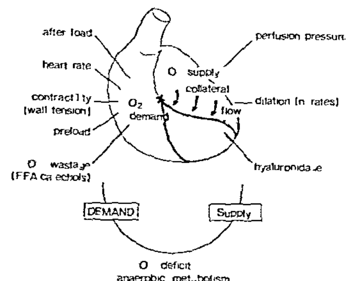

Fig 3 *Hemodynamic factors of importance in the genesis of ischemia. In regional ischemia (infarcting myocardium) there is a balance between the oxygen demand and the oxygen supply The oxygen demand exceeds the oxygen supply and there is an energy deficit. The oxygen demand depends largely on the contractility of the heart, the heart rate and the afterload but metabolic factors may play an important role "Oxygen wastage" refers to those metabolic processes which impair the conversion of oxygen taken up to ATP available for contractile purposes. The oxygen supply depends largely on the collateral flow which in turn depends on the difference between the coronary perfusion pressure and the intramyocardial pressure, and the degree of coronary vasodilation (which may be possible by increased use of nitrate) It is also possible that hyaluronidase increases the permeation of nutrients brought to the infarcting tissue by the collateral flow (Reproduced by permission of Postgraduate Medical Journal.)*

restoration of normal blood flow to the ischemic zone whether surgically or by reversal of experimental occlusion would inevitably bring about an improvement Indeed that assumption underlines the recommendation of a recent panel that acute coronary occlusion should be treated aggressively by coronary bypass as soon as possible and within [illegible] hours of the event [illegible] However reperfusion after 40 minutes of experimental coronary ligation greatly accelerates ischemic damage[54] and in [illegible] promotes calcium uptake[5] with harmful [illegible] mitochondria[55] After 90 minutes of severe [illegible] ischemia this capacity for calcium up[illegible]ochondria is lost presumably because [illegible] of mitochondria damage[56] and it [illegible] presumably be safer to reperfuse However [illegible] situation in patients with infarction with [illegible] degrees of coronary occlusion variable collateral circulation and possibly the further complication of arterial spasm cannot readily be assessed The occurrence of contraction band necrosis following coronary artery bypass graft surgery may reflect re[illegible] damage It would seem prudent to bear in mind that reperfusion may be harmful especially in the early phases of ischemic damage while late reperfusion may not be successful

Once ischemia has developed a further series of events (summarized in Figs 2 and 4) can be provoked to produce increasing ischemia [illegible] ultimate infarction

2 Role of hemodynamic factors (Fig 3) The hemodynamic factors controlling the oxygen uptake of the heart are well established[illegible] include the afterload (approximately represented by the arterial systolic pressure) the heart rate and the contractility of the heart The preload plays a lesser role because volume work is not so energy requiring as pressure work[5] However an increased preload could further dilate a fail[illegible] myocardium thereby increasing the wall tension and hence the oxygen demand It is proposed that these factors could (1) produce ischemia in the presence of a compromised blood supply and (2) promote the transition from ischemia to infarction and increase infarct size[illegible]

That such hemodynamic factors can influence the myocardial oxygen uptake is firmly established That they could influence the progression from ischemia to infarction depends on the hypothesis that there is a *balance between the oxygen supply and demand* of the ischemic zone (Fi[illegible]) which can be tipped in either direction with consequent sparing or increased injury to the critically jeopardized or vulnerable cell[illegible] their ultimate survival or necrosis This point of view calls for (1) the existence of a zone of intermediate blood supply (2) a collateral blood supply to the severely ischemic tissue and (3) the persistence of some contractile activity in ischemic tissue The existence of tissue with these intermediate properties has been held to constitute a *border zone* Moving inward from the visible edge of the cyanotic area produced by coronary artery ligation severe and progressive derangements of metabolism flow and electrocardiographic changes have been found [illegible] (see also reference of Hearse and colleagues) The [illegible] ischemic tissue and the border zone in the [illegible] also retain some contractile properties [illegible] In the

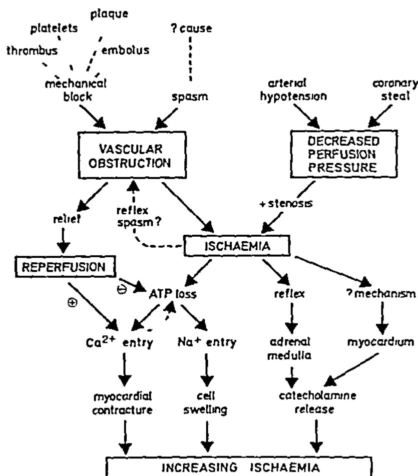

Fig 2 The classical cause of ischemia is vascular obstruction caused by a mechanical block, the latter in turn generally resulting from a thrombus. However coronary artery spa m may also play a role Either by lysis of the thrombus or by relief of spasm reperfusion may take place with decreased loss of ATP (impro ed oxygenation) but increased entry of calcium which can aggravate ATP loss Ca entry is held to be causative in the development of ischemic contracture which increases ischemia Ischemia can also provoke cell swelling and/or catecholamine release which also increase the severity of ischemia A decreased coronary perfusion pressure especially in the presence of coronary artery stenosis may be another theoretical cause of ischemia.

occlusion could cause reflex vasospasm through an adrenergic mechanism was suggested by Grayson and colleagues although their method of measuring coronary flow has now been superseded

Experimentally the degree of *collateral circulation* influences the extent and severity of the infarction process in the presence of a well developed collateral circulation coronary occlusion may have no effects Much attention has been paid to the possibility that part of the beneficial effect of nitrates in decreasing the severity of ischemia could be by augmentation of collateral flow in animals with either acute coronary occlusion or chronic coronary narrowing [50] In patients collaterals would be required to deliver the therapeutic agent to the ischemic zone which could explain why Gold and associates [1] found a beneficial effect of propranolol especially in those patients with angiographically demonstrable collateral vessels Theoretically the presence of collaterals should limit the severity of infarction in man although Baroldi and Scomazzoni[55] have argued to the contrary on the basis of postmortem dissection and case anal of the coronary circulation in mate However they did not quant t size

It might be supposed tha sion

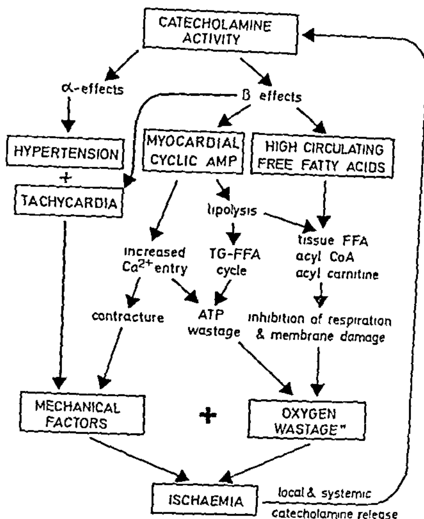

Fig 4 Catecholamines can increase ischemic injury by (1) mechanical factors such as hypertension (chiefly an α-effect) and/or tachycardia (chiefly a β-effect) (2) promotion of ischemic contracture with decreased blood flow as a result of increased calcium entry and (3) metabolic effects The latter include the effects of increased circulating free fatty acids and increased cardiac lipolysis which may cause (1) metabolically futile cycles such as the postulated triglyceride free fatty acid (see Opie) and (2) accumulation of tissue lipid metabolites These lipid changes lead to oxygen wastage (Section 2 of this report) through mechanisms not yet well defined Once ischemia is established generalized or localized release of catecholamines can lead to further catecholamine activity and a metabolic vicious circle TG = triglyceride FFA = free fatty acid Acyl CoA = long-chain acyl CoA eg palmityl CoA

intracellular passage of a macromolecule horse radish *peroxidase* An effect on cell permeability may explain why low doses of noradrenaline could induce enzyme release from the isolated heart even in the absence of major loss of high energy phosphate compounds although it remains true that high doses of catecholamines cause substantial depletion of energy as first pointed out by Fleckenstein

The effect of catecholamines on *lipolysis* warrants further consideration The myocardial oxygen consumption in a catecholamine stimulated heart can be reduced by about 30% by an antilipolytic agent When the metabolic "oxygen wastage" caused by noradrenaline is inhibited by an antilipolytic agent then ST segments over the ischemic myocardium fall rather than rise Furthermore when an inotropic stimulus equivalent to that of isoprenaline is applied to the ischemic heart by glucagon or by calcium then there is less epicardial ST segment elevation Dopamine is also a fatty acid mobilizing agent

chemic zone flow must be reduced to zero efore oxidative metabolism ceases[61] hence the emonstration of at least some collateral flow in nimal models[61 65-67] and in some patients with cute myocardial infarction[51] supports the oxy en balance theory The existence of a clearly efined border zone albeit narrow implies that herapeutic salvage of that zone could decrease he ultimate infarct size by between 35% and 65% hese are rough calculations but give an idea of nagnitude[61]

However the *oxygen imbalance hypothesis an be criticized* Chance s group [?] has argued hat the gradients for oxygen are very steep and hat mitochondria respond to oxygen in an all r none fashion thus the oxygen border zone is xtremely narrow Furthermore 24 hours after oronary ligation the border as defined by mea urements of tissue creatine kinase is narrow and consists of a mixture of normal and abnormal cells Such arguments can be countered Thus even the Chance model allows for the existence of an intermediate cell [64] and the absence of a border zone at 24 hours does not exclude one at 25 minutes Nevertheless it must be noted that the border zone concept has been challenged

A major criticism of the oxygen supply versus demand theory is that in very few studies if any have both the oxygen uptake and the infarct size been measured under the influence of a thera peutic agent And even if the over all myocardial oxygen uptake were known that does not neces sarily reflect changes in a similar direction in the critical oxygen uptake of the border zone However on the whole agents which *theoretically* change the myocardial oxygen uptake have sub sequently been shown to change the infarct size in a similar direction[1]

3 Role of catecholamines (Fig 4) Raab and associates[71] made the basic observation that the infusion of catecholamines could precipitate fea tures of regional ischemia in an experimental preparation with compromised coronary circula tion Since then much evidence has supported the concept that catecholamines can exaggerate the degree of myocardial ischemia although dose effects and the relative balance between α and β effects cause complex results [?] Thus pure β stimulation by isoprenaline increases ischemic injury[6] and infarct size in dogs whereas com bined α and β stimulation by noradrenaline decreased the extent of ischemic injury presum ably because the beneficial effects of an increased coronary perfusion pressure outweighed the harmful effect of an increased afterload[?] or because other unspecified beneficial effects could be achieved by low doses of noradrenaline in the absence of systemic hypertension[?] and despite elevation of circulating free fatty acids [?] But it must not be assumed that α-effects are necessari ly beneficial Methoxamine given in similar doses decreased infarct size in one series[1] and exagger ated ischemic injury in another[6] These effects of dosage and of comparative stimulation of α and β receptors are not yet well understood

β-effects of catecholamines appear to be harm ful to the ischemic myocardium and the mecha nisms involved may include (1) an increased heart rate[? ?] (2) increased circulating free fatty acids [?] and (3) the effects of an increased intracellular cyclic AMP level Cyclic AMP is fundamentally involved with the *entry of calcium ions into myocardial cells*[77] *Increased entry of* calcium ions could in part explain the phenome non of oxygen wastage found in a classical study by Lovatt Evans[73] Uptake of calcium by mitochondria is energy requiring and occurs as an alternative to oxidative phosphorylation[79] In creased calcium entry may also be harmful by provoking myocardial contracture with compres sion of the blood supply Another postulated mechanism whereby cyclic AMP in excess could harm the heart is by *stimulation of lipolysis* in the heart the resultant liberation of long chain free fatty acid could in the presence of α glycerophos phate derived from glycolysis [?] promote re-esterif ication of fatty acid to triglyceride with the operation of a triglyceride-fatty acid cycle[77] which is energy wasting

Yet another mechanism to produce oxygen wastage could be by *accumulation of products of fatty acid metabolism* in the tissue (tissue free fatty acid acyl CoA and acyl carnitine) these compounds can inhibit respiration[83] and cause membrane damage Even if oxygen does reach the ischemic mitochondria it need not be efficiently used Thus there are problems not only with the oxygen supply but also with the conversion of the available oxygen to energy

Besides mechanical factors and oxygen wast age catecholamines may also act by *increasing cell permeability* which occurs within 10 minutes of the exposure of the healthy animal heart to high doses of catecholamines as evidenced by the

cholamines on the infarction process Isoproterenol (0.25 to 0 50 µg/kg /minute) increases depletion of myocardial creatine kinase an indirect marker of the extent of necrosis[3] there is enzyme depletion in those sites which are not involved by coronary occlusion alone—i e the infarct has extended The dose of isoproterenol is similar to the estimated rate of secretion of catecholamines in patients with acute myocardial infarction[84] Even spontaneous rates of secretion of adrenaline *after coronary ligation in dogs are able to promote* damage away from the ischemic zone as shown by histochemical changes[93] In the isolated rat heart noradrenaline 10 M or higher is able to induce ultrastructural changes including hypercontracted cells[11] a type of lesion found especially around the edge of the human infarcts[1] and presumably also the result of catecholamine secretion

In high doses catecholamines can produce large scale infarct like necrosis even in the total *absence of coronary arterial narrowing*[94] Whether such massive doses of catecholamines could ever be secreted in response to extreme stress or other factors and hence account for some cases of infarction occurring without coronary artery disease is a matter of speculation

If however catecholamines can initiate or extend ischemic injury and ischemic injury can provoke release of catecholamines then a harmful vicious circle would be set up (Fig 4)

Progression from ischemia to infarction (Fig 5)

At a cellular level the harmful effects of ischemia are a combination of (1) poor oxygen delivery leading to depressed mitochondrial production of ATP and an accumulation of fatty acid metabolites and (2) poor washout of lactate protons and carbon dioxide which can all contribute to the severity of ischemic damage

1 Effects of poor oxygen delivery From the clinical point of view large scale enzyme release from the heart is virtually synonymous with cell necrosis—i.e myocardial infarction as opposed to other chest pain syndromes hence it would be useful to establish which metabolic events underly the liberation of enzymes from the heart In a number of simpler model *ATP depletion* can be related to the extent of enzyme release Thus the extent of fall of tissue ATP in the perfused anoxic dog heart correlates very well with the amount of enzyme released However in regional ischem (developing experimental myocardial infarct substantial tissue depletion of ATP can occu. 1 minutes after ligation before the tissue conte creatine kinase had decreased[96] More probab may be a subcompartment of ATP more re accessible to the cell membrane which h special role in the maintenance of cell membra integrity as argued by Bricknell and Opie[97] ATP is produced by glycolysis and the e is go *electrophysiological evidence for the role of* ATP in another membrane associated eve namely the production of the normal act potential Thus increased provision of glycol ATP may be one way whereby glucose is a n favorable fuel for the infarcting myocard. than is fatty acid

The observation that glucose decreased a free fatty acid increased enzyme release from t coronary ligated rat heart[99] is consonant with t above hypothesis but by no means provides di evidence In fact the beneficial effects of glucos and the harmful effects of fatty acids extremely complex In severely ischemic ti the rate of glucose uptake and glycolysis inhibited by the severity of the ischemia hence the above relationship probably hold o for mildly or moderately *ischemic tissue* and for severely ischemic tissue

The mechanism of *fatty acid toxicity* incl the intracellular accumulation of free fa acid[10] acyl CoA[3] acyl carnitine[1] and ly phospholipid Early work stressed the pos ity that accumulation of free fatty acid in tissue (secondary to impaired oxidation) co cause uncoupling and thereby "oxygen wa age more recently accumulation of the ac vated fatty acid metabolite long-chain acyl Co *has been found* and emphasized as a cause impaired utilization of oxygen so that tran ADP into the mitochondria is blocked as transfer of ATP outwards However acyl Co accumulation should depress mitochondrial o gen uptake whereas it is usually "oxygen wa tage which is *held to be* an effect of exc provision of fatty acids during ischemia (Opie)

Of the other effects of fatty acid metabol those on the membrane are a rather nonspec but nevertheless important effect which co contribute to lysosomal *activation* (see lite Inhibition of the membrane ATPase (Na /K

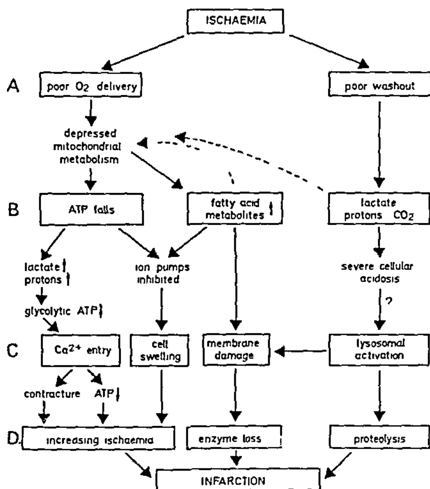

Fig 5 Proposed metabolic mechanisms whereby ischemia can produce infarction *Panel A* shows the two major effects of ischemia namely poor O delivery and poor washout of metabolites *Panel B* proposes that depressed mitochondrial metabolism results in decreased production of ATP and accumulation of fatty acid metabolites (see *Fig 4*) which are normally metabolized in the mitochondria Anaerobic metabolism causes accumulation of lactate and protons (the latter from breakdown of ATP) and continued residual respiration causes accumulation of CO *Panel C* proposes that decreased production of glycolytic ATP (a result of accumulation of lactate and/or protons) results in increased calcium entry Inhibition of ion pumps by lack of ATP and by inhibition of fatty acid metabolites results in sodium and water retention and cell swelling Fatty acid metabolites also probably cause membrane damage which may also result from lysosomal activation as a result of a severe cellular acido is or possibly as result of other mechanisms such as ATP depletion [20] *Panel D* proposes that the final events leading up to infarction may be increasing ischemia caused by ischemic contracture and cell swelling enzyme loss from membrane damage and proteolysis from lysosomal activation [29]

and increases ischemic injury more than an equivalent inotropic response obtained by calcium That oxygen wastage may exaggerate the effects of ischemia in man is suggested by the finding that in patients with coronary artery disease increased fatty acid uptake accounts for half of the increase of myocardial oxygen uptake which results from catecholamine stimulation the other half being due to tachycardia

In patients with acute myocardial infarction plasma catecholamine values are about 1 to 5 µg/L plasma (see Vetter and colleagues[90]) Such concentrations greatly increase ischemic damage in isolated rat hearts The cause of the increased catecholamine concentrations is not clear but may include psychological stress (see Opie[7]) and reflexes originating in the border zone of the infarcting tissue[8]

The data reviewed thusfar indicate complex effects of catecholamine stimulation on *ischemic* injury with the majority of effects being harmful Less work has been done on the *effects of cate*

before there is total depletion of energy Once taken up calcium can accumulate in the mitochondria and can contribute to the development of ischemic contracture usually an irreversible event[56] *More direct evidence for the postulated* role of calcium in irreversibility has been obtained with a lanthanum probe lanthanum is a trivalent ion with properties resembling those of calcium but not normally found within the cell With progressive hypoxia of the cat papillary muscle, lanthanum can be found at intracellular sites of high calcium affinity as ultrastructural changes develop after 2 to 3 hours of hypoxia[106]

However in experimental infarcts in dogs it is doubtful that massive calcium uptake is the critical event accompanying or causing irreversibility, because (1) scans for ^{99}m technetium stannous pyrophosphate are negative 7 hours after occlusion but strongly positive after transient occlusion[107] (2) uptake when found is especially localized to the border rather than to the central zone of the infarct[08] and (3) the uptake of the label does not appear to be directly related to the severity of necrosis[1] The effectiveness of calcium antagonist drugs in reducing the size of experimental infarcts[110] also does not prove the role of calcium in the pathogenesis of infarction because such drugs have multiple effects including for example relaxation of the coronary arteries

In patients increased calcium uptake does not *appear to occur very soon after the induction of ischemia by coronary vasospasm as shown by the* fall rather than the rise of dp/dt max in patients during an episode of ST elevation Nevertheless increased calcium entry may be an important initial event in the pathogenesis of other types of myocardial ischemia as suggested by Harris[8]

Thus although increased uptake of calcium into the heart cell is generally held to be an *adverse effect of ischemia and could help to* promote or cause permanent damage especially after reperfusion yet the evidence incriminating calcium is not yet firm and the use of calcium antagonist drugs is still in the early stages of investigation

2 Effect of poor washout There are major metabolic differences between hypoxia with maintained cell perfusion (eg depriving a perfused heart of its oxygen supply) and ischemia (with poor washout plus metabolite accumulation) The classic effect of poor washout is the accumulation of *protons* (Fig 6) for example from anaerobic glycolysis with ATP breakdown or from a variety of metabolic cycles which can also produce protons[8] Although severe acidosis *must be harmful to the cell* some evidence[11] [11] suggests that milder acidosis can protect the hypoxic cell by keeping out calcium (protons and calcium ions can compete for superficial binding sites)

Less well publicized are the effects of accumulation of other metabolites Thus retention of *carbon dioxide* partially as the result of continued residual respiration[64] may contribute to *impaired contractile activity soon after coronary* artery ligation[112] *Lactate* accumulation may help inhibit glycolytic flux[114] and thereby minimize the beneficial effect of provision of glucose in zones of severe ischemia Lactate may also contribute to mitochondrial damage and may shorten the action potential duration[11] [115] Finally accumulation of *NADH* in the mitochondria and cytoplasm as an effect of impaired oxidative metabolism will *depress citrate cycle activity*[8] and impair the capacity to use such oxygen as is available This mechanism together with mitochondrial depression induced by acyl CoA could explain why the cell can undergo metabolic deterioration even though oxygen may still be reaching the infarcting tissue by collaterals[8]

A cogent hypothesis linking accumulation of metabolites with cell death is the *lysosomal hypothesis* according to which ischemia causes *accumulation of protons* and of membrane active fatty acids which in turn reduces membrane integrity including that of the lysosomes Thereafter lysosomal enzymes leak out[117] cellular constituents including critical components of the cell membranes are attacked by these lysosomal enzymes and cell necrosis is initiated or accelerated[11] Although it cannot be stated with certainty that lysosomal changes are the cause and not the result of a critical stage in myocardial cellular damage yet there is a coincidence in time between lysosomal activation and the appearance of ultrastructural changes of irreversibility[1] Further weight *is given to the* lysosomal hypothesis by the effects of methylprednisolone and glucose in stabilizing lysosomes and in reducing ischemic or hypoxic damage in a variety of models[11] [21] At present the side effects of these agents in impairing wound healing *limit* their testing in man but the possibility of new analogs without

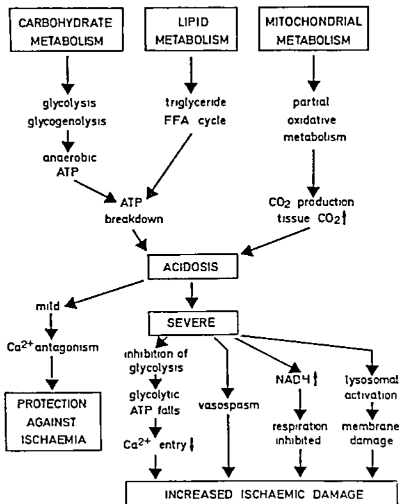

Fig 6 During ischemia protons can be produced as result of carbohydrate or lipid metabolism or mitochondrial respiration The mechanisms involved are (1) activation of glycolysis with production of anaerobic ATP and (2) activation of triglyceride breakdown with simultaneously an increased incorporation of free fatty acids (FFA) into triglyceride—i.e the triglyceride FFA cycle In either case breakdown of ATP occurs and protons are liberated An increased tissue pCO resulting from partial oxidative metabolism can together with protons formed from ATP breakdown cause an intracellular acidosis If mild the acidosis may protect from ischemia by calcium antagonism but if severe increased ischemic damage may result by (1) inhibition of glycolysis and decreased calcium entry (2) acidosis-caused vasospasm (3) inhibition of mitochondrial respiration by NADH and (4) lysosomal activation

can be achieved by low concentrations of acyl carnitine which also accumulates in ischemia These membrane effects may together with early loss of ATP explain the rapid potassium loss after coronary ligation

Loss of *potassium* and gain of *sodium* can be detected within minutes of coronary ligation by coronary venous changes but significant tissue depletion of potassium takes hours to develop Associated with sodium retention is edema formation recently stressed as a cause of the no reflow phenomenon whereby increased swelling of myocardial cells can impinge on the vascular bed and diminish blood flow even if reperfusion were achieved by release of coronary occlusion

A further working hypothesis is that ATP is required for the activity of those ionic pumps which maintain the cellular balance of *calcium ions* Calcium accumulates in cells damaged by ischemia especially after reperfusion The uptake of calcium by mitochondria is energy wasting and must be occurring in the prenecrotic phase

20 and 40 minutes From these points of view, it is of interest that 6 hours post ligation the central infarct zone has an ATP value of below 1 μmoles/g with severe depletion of total adenine nucleotide and of glycogen, but the infarct edge has values of 1 20 to 1 8 μmoles/g and the peri infarct zone has values of 2 to 3 μmoles/g [64] and the glycogen is near normal These indirect arguments suggest that by 6 hours only the peri infarct tissue and perhaps some of the infarct edge is potentially salvable Other information shows[1 7] that 1 to 4 hours after acute coronary ligation in dogs, epicardial ATP even in the central infarct zone is still dropping to the critical levels Four hours post ligation the endocardial zone has developed changes in the K /Na ratio compatible with necrosis with the appearance of mitochondrial dense bodies whereas the epicardial zone has much milder changes and still constitutes a border zone [1 8]

Although indirect evidence links the severity of ATP depletion to irreversibility major reservations are (1) in some situations it is loss of production of glycolytic ATP and not the severity of over all cellular ATP depletion that can be related to the severity of ischemic injury[97 1 9] (2) ATP depletion may merely be a nonspecific index of cell damage and other cellular events[1 9] such as glycogen depletion or potassium sodium changes or activation of lysosomal enzymes[117] can also be circumstantially linked to the onset of necrosis Thus the severity of ATP depletion *should be viewed only as an index of the severity* of ischemic damage The very complex events surrounding the onset of necrosis remain imperfectly understood

Taking into account the evidence based on rates of ATP depletion [7] ionic changes [0 10 1 5] glycogen depletion [1 9] mitochondrial calcium uptake lysosomal activation (see references to Figs 5 and 6) the commencement and pattern of cardiospecific enzyme release [29 3 1 9b] and the rate of onset of Q wave formation [6 6] it is reasonable to conclude that (1) *early irreversible damage* starts about 20 to 40 minutes after complete coronary occlusion in animals and within 2 hours of the onset of symptoms in patients (2) *irreversibility progresses* over a period of several hours as judged by the rate of progression of cellular metabolic changes and enzyme release and Q wave format[illegible] and (3) there is therefore a perceptible pe[illegible]d of several hours duration during which *therapeutic intervention* can be attempted

Basic considerations conclusions

Factors concerned with the initiation of ischemic injury and the progression of such injury to infarction are (1) vascular factors including the role of the controversial thrombus (?) hemodynamic factors *including the hypothesis that* there is a balance between the oxygen supply and demand in the ischemic zone and (3) catecholamine activity, which is generally harmful to the developing infarct, although there are important dose effects and complexities introduced by the relative effects of α and β stimulation The cellular events concerned with the change from ischemia to infarction include ATP depletion, accumulation of fatty acid and acyl CoA alterations in ions including calcium the retention of metabolites (protons carbon dioxide and lactate) and lysosomal activation

There is an important difference between *ischemia* a reversible event and *necrosis* or infarction which is irreversible Experimentally a decreased blood supply or increased hemodynamically induced oxygen demand or increased catecholamine activity can worsen the severity of the ischemic process and the extent of the ultimate infarction However the difficulty in assessing infarct size even in experimental preparations has led to the use of indirect indices of necrosis (ECG changes tissue enzyme *depletion) The existence of a border zone and of cells of interme*diate metabolic characteristics (neither totally healthy nor dead) for anti infarct agents to act on seems probable but by no means proven A general metabolic response further alters the metabolic patterns in the ischemic zones

A consideration of the time scale involved suggest that therapeutic intervention could be justified for at least some hours post coronary ligation or after the onset of symptoms [illegible] patients However in most severely ischemic zones irreversibility would already have set in by 20 to 40 minutes after complete coronary occlusion

an effect on wound healing suggests that membrane stabilization will eventually be tested clinically

Role of general metabolic response in acute myocardial infarction (Fig 7)

In addition to the above events (chiefly described in experimental animals) there is in patients the development of a general metabolic response associated with acute myocardial infarction[1,2] The major components are glucose intolerance[123] increased catecholamine secretion and raised blood free fatty acids Each of these changes could contribute to the progression of ischemic damage (Fig 7) and the catecholamine and fatty acid changes could contribute to the development of arrhythmias (see Opie[7])

Time scale for irreversibility

When does irreversibility set in? Data based on the response to reperfusion after coronary ligation or global ischemia are not necessarily reliable because (1) reperfusion hastens the development of ischemic damage[5] and (2) ischemic damage has a graded and not a global effect depending on the extent of the collateral flow Thus the point of no return must be defined for regional ischemia without reperfusion From the metabolic point of view the changes that have been emphasized in this review are the transition from ischemia to infarction with a fall of ATP increased fatty acid metabolites and the accumulation of lactate protons and CO_2 with a severe intracellular acidosis (Fig 5) with further limitation of flow from edema formation and Ca^{2} contractures Limited information is available about the time scale of such changes in experimental myocardial infarction Over the period 1 to 6 hours post ligation lactate no longer rises (probably because of continued washout by collateral flow) and the pH change is slight but there is progressive depletion of ATP[6] not so much in the central zone but in the border zones[6] Substantial accumulation of fatty acid metabolites probably occurs within one hour[83] Of the major metabolic changes it may be progressive depletion of adenosine triphosphate that becomes critical

On theoretical grounds Kubler and Spieckermann[176] proposed that when the ATP decreases to 2 μM/g (33% of control) no recovery from severe global ischemia can occur Jennings and co workers[27] find that in severely ischemic posterior papillary muscle preparations in which collateral blood flow is less than 10% of control the critical ATP is about 20% of normal—i e about 1.2 μM/g and the critical survival time is between

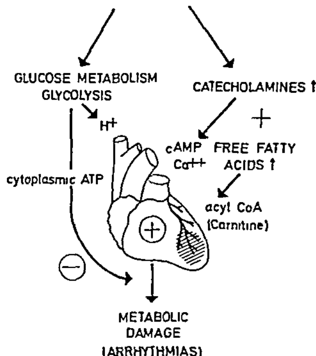

Fig 7 Schematic representation of effects of general metabolic response in acute myocardial infarction on the severity of metabolic damage and the development of arrhythmias. The general metabolic response includes glucose tolerance increased catecholamines and high blood free fatty acids These general metabolic changes can increase metabolic damage (indicated by + sign) and possibly help provoke arrhythmias Catecholamines may exert an effect at a cellular level by cyclic AMP calcium changes and by mobilizing free fatty acids (see *Fig 4*) Free fatty acids may act by intracellular accumulation of acyl CoA carnitine has an important role in the transport of acyl CoA into mitochondria[25] Increased glycolysis can be induced therapeutically by administration of glucose and insulin In severely ischemic tissue protons (H) accumulate and are derived from ATP produced by glycolytic flux Protons do not accumulate to the same extent in moderately ischemic cells because the predominant pattern of metabolism is still oxidative[84] In moderate ischemia increased production of cytoplasmic ATP by promotion of glycolysis may speculatively inhibit the extent of metabolic damage Several agents promoting metabolic damage may also in specified conditions provoke arrhythmias and some antiarrhythmic agents may lessen the extent of ischemic damage (see *Section 2 of this report*) (Based on Bricknell and Opie[9] by permission of the University Park Press)

and the late rightward forces do not reach one millivolt in magnitude the likely choice is posterobasal infarction Further caution must be applied in this situation as anterior fascicular delay may be present in the complete absence of coronary disease or infarction

In a very recent study echocardiography proved to be a highly useful discriminant in identifying patients with dilated right ventricles or with hypokinetic posterior left ventricular walls enabling better separation of RVH from posterobasal infarct cases than was possible from vectorcardiographic considerations alone[9]

Left ventricular hypertrophy and pseudo infarction

The posterior QRS addition to QRS voltage which occurs in left ventricular hypertrophy may mimic anterior myocardial infarction[117, 145, 158] Early posterior addition may reduce the duration and magnitude of the normal early anterior forces to very low values or to zero In addition advanced LVH as described previously, may in its most advanced form result in a clockwise horizontal loop[41, 49] Thus the picture of extensive anterior infarction may be closely mimicked Several authors have studied this problem and all agree that the usual diagnostic criteria for anterior infarction are much less sensitive in the presence of left ventricular hypertrophy especially when this is the result of aortic valve disease[1, 145, 15] Therefore when the vectorcardiographer reviews a horizontal QRS loop lacking anterior forces and presenting with marked posterior orientation and even with clockwise rotation he should suspect a pseudo infarction if the QRS voltage is high suggesting concomitant left ventricular hypertrophy

Unfortunately neither the direction nor the rotational characteristics of the T loops in these cases serve as a useful discriminant between severe left ventricular hypertrophy and LVH accompanied by anterior infarction[06, 2]

Uncommonly the frontal loop in severe left ventricular hypertrophy may mimic inferior myocardial infarction with an upward bowing of the first half of the QRS loop which may remain superior for 30 msec thus mimicking a diaphragmatic infar[illegible] These loops are probably somewhat more c[illegible] when the left ventricular hypertroph[illegible] basis of aortic insufficiency than aortic [illegible] although both lesions may

result in a pseudo inferior infarction picture

Cardiomyopathies of various etiologies may mimic myocardial infarction vectorcardiographically[140, 142, 143, 1, 5, 151] The markedly hypertrophied intraventricular septum seen in hypertrophic subaortic stenosis is believed to be responsible for the marked initial rightward anterior forces which may occur in that condition and which may mimic dorsal or lateral infarction

However at least one study denies that any significant difference exists between the left ventricular hypertrophy patterns resulting from aortic stenosis aortic insufficiency or hypertrophic cardiomyopathy[41]

Certainly the myocardial deposits or scarring which occur in infiltrative cardiomyopathies such *as sarcoidosis or amyloid disease* may result in QRS loop deformities and bites which are indistinguishable from those seen in coronary disease and myocardial infarction[11, 1, 1, 11, 11]

The congestive cardiomyopathies may present with a wide variety of vectorcardiographic abnormalities particularly conduction disorders including hemiblocks and simple axis shifts[1] However in many such cases mimicry of myocardial infarction in any location occurs

In cardiomyopathies the combination of conduction disturbance small areas of fibrosis and ventricular hypertrophy can readily lead to distortions of the activation sequence leading to QRS loop deformities readily mistaken for those of myocardial infarction An interesting variant is seen in the mitral valve prolapse syndrome in which coronary disease is absent but myocardial contractile abnormality is frequently present Although the QRS loops in these patients are commonly normal an occasional patient will present with complete absence of anterior forces resembling anterior myocardial infarction

Another variety of cardiomyopathy which presents a rather typical pseudo infarction pattern is Duchenne s muscular dystrophy in which pathological changes occur in the posterobasal wall of the left ventricle[50] As might be expected this results in an anterior displacement of the QRS loop which thus could be misinterpreted as true posterior infarction

The pre excitation (WPW) syndrome in which initial QRS activation may be directed markedly anterior posterior or superior and thus may mimic anterior posterior or inferior infarction will be discussed in a separate section

Fundamentals of clinical cardiology

Clinical vectorcardiography in adults Part 2

Pulmonary emphysema and pseudo anterior infarction

The effects of emphysema on the distribution of QRS forces on the torso surface has been mentioned previously in this review The resultant decrease in anterior QRS forces which may be simulated by experimental overinflation of the lungs may result in a scalar ECG and a vectorcardiogram resembling anterior myocardial infarction owing to the poor progression of scalar precordial R waves and the minute duration and magnitude of anterior forces recorded Watanabe and associates have studied this problem using computer techniques and multivariate statistical analysis Four vectorcardiographic measurements were selected to enable the best discrimination between these two conditions The location of the 15 msec vector in Lead Z (anterior or posterior) was one useful criterion The mean value for anterior duration was 30 msec in the emphysema group but only 14 msec in the anterior infarction group The authors found that 25 msec provided a good discriminating point The second criterion used was the ratio of the rightward forces (Sx) divided by the sum of the leftward plus rightward forces (Rx + Sx) This value was 0 417 in the chronic obstructive lung disease group and 0 245 in the anterior infarction group—indicating a greater relative strength of rightward voltage in the emphysema patients

The third criterion which separates the groups was the simple voltage summation of Rx + Rx (leftwards plus posterior forces) This value was 0 85 in the emphysema group but 1 6 in the anterior infarction group Finally the total QRS duration was a fourth useful discriminator with a mean value of 93 msec in the emphysema group and 105 msec in the myocardial infarction group Despite the use of these criteria the greatest difficulties are encountered in patients with emphysema whose anterior forces are completely absent This may occur although infrequently in the absence of coronary disease or myocardial infarction and it poses a sometimes impossible differential diagnosis

Although considerable overlap was encountered by all investigators who have approached this problem it seems apparent that the use of multiple criteria rather than any single one is best in attempting to separate the two conditions Mitral stenosis which often results in a small posteriorly oriented QRS loop with terminal forces oriented to the right may also present difficulties in discrimination against anterior infarction Fortunately clinical features and the age and sex of the patients are frequently very valuable in making a preliminary differentiation in mitral stenosis whereas the patients with chronic obstructive lung disease are often clinically very like patients with anterior infarction

Pseudo infarction with right ventricular hypertrophy

Since right ventricular hypertrophy adds both anterior and rightward QRS forces the pseudo infarction frequently diagnosed is posterior lateral in location The differential diagnosis between right ventricular hypertrophy and posterobasal infarction has been presented by several authors If the major QRS axis is in the left anterior quadrant of the horizontal plane

that this may occur in subjects free of right ventricular hypertrophy or posterior myocardial infarction

Superior and inferior divisional blocks (references 2 to 16 173 to 188)

Rosenbaum s concept of the trifascicular ventricular conduction system *consisting of the right* bundle branch and a left branch *composed of two* divisions has received a wide acceptance as has his terminology for conduction disorders in the divisions of the left bundle as anterior and posterior hemiblock[173] The characteristic electrocardiographic and vectorcardiographic alterations induced by poor conduction in the divisions of the left bundle have been reproduced by intracoronary injections[17 177 178] and by *surgical* interruption in animals and in humans *intermittent* conduction disorders have been observed in some subjects[177 1 0] Rosenbaum s contribution to the understanding of ventricular conduction disorders is *extremely important* However, two aspects of his conception and terminology probably require *refinement* All the diagnostic features which will be described for fascicular blocks are derived from the frontal *reference* plane, owing to *changes* in the Y axis[174] *Very simply* stated a markedly *superior* shift in the frontal plane corresponds to superior divisional block or, in Rosenbaum s terminology *left anterior* hemiblock On the other hand a markedly inferior *and somewhat rightward shift* occurs with inferior divisional block referred to by Rosenbaum as left posterior hemiblock[173] Since neither the anterior or *posterior* directions are reflected in the *frontal reference* plane the *terms* anterior and posterior to describe these changes are probably inappropriate and should be replaced by superior and inferior

Anatomical studies in recent years have confirmed that the left bundle branch ramifies more extensively than previously thought with a third or anterior fascicle commonly present Obviously the *term* hemiblock does not properly fit a trifascicular *division* of the left bundle branch[95] Instead of hemiblock the term divisional *block* seems more appropriate as it allows characterization of [illegible]nduction disorders in the third or anterior f[illegible] and even leaves room for future anato[illegible] dis[illegible]ries

For these r[illegible] [illegible]he portions of this review dealing with d[illegible] [illegible]locks of the left bundle the terms sup[illegible] [illegible]ional block and inferior divisional block will be used rather tha[illegible] the more commonly accepted *hemiblocks*

Readers are reminded that for decades myocardial infarctions on the diaphragmatic surface of the left ventricle were referred to as posterior infarcts and that many years of educational activity were necessary before the term inferior infarction was accepted Posterior infarction *has come to mean* infarction of the posterobasal *segment of the left ventricle* and is quite distinct *from* inferior infarction[3 8] Anterior divisional block does exist but it results appropriately in *an anterior* shift of QRS which may be quite distinct *and separate* from a superior axis shift—as discussed in a prior section The typical vectorcardiographic changes of superior or inferior *divisional* block uncomplicated by other pathology, are easy to describe and to understand Excellent descriptions and examples may *be found* in all of the general references given in the first section of this review [8] In superior divisional block the major change is a shift of the major axis of the frontal plane loop to a markedly superior position lying above the X axis and commonly well above The rotation is always counterclockwise The initial forces in uncomplicated superior divisional block are almost invariably directed to the right and inferiorly owing to unopposed activation of the septum from the uninvolved branches of the conducting system resulting in a distinctly more inferior orientation *than is usual for normal* early activation[' 1..]

This markedly inferior and rightward orientation of initial vectors is responsible *for* one of the diagnostic dilemmas occasionally encountered in uncomplicated superior divisional block[..] *This is the appearance of small but distinct* Q waves in the right precordial leads particularly in Leads V_2 and V_3[94] The Q waves result because the initial *forces as described above are oriented* so inferiorly as to register as negative deflections in the precordial lead axes

The horizontal *loop* however exhibits its usual smooth counterclockwise course with the major vectors oriented left and *posterior* as in the *normal case In patients with* intermittent superior divisional block slight prolongation has commonly been observed but never *beyond the upper limits of normal*[...] Terminal "cluttering" of time dashes is sometimes also seen These observations indicate that *the disorder is indeed a conduction* delay

Inferior divisional block produces the expected

Infarction and pseudo infarction after coronary bypass surgery

Between five and 25% of patients undergoing coronary artery bypass surgery develop new Q waves postoperatively commonly attributed to postoperative myocardial infarction Vectorcardiographic study has been performed pre and postoperatively in such patients and a higher recognition rate for infarction has been claimed for the vectorcardiogram[153, 15]

However it should be pointed out that QRS voltage changes may occur as a result of alterations in postoperative hematocrit rather than true cardiac pathology[152] Further when new Q waves are correlated with bypass graft patency and postoperative ventriculograms some patients with new Q waves are found to present with patent grafts to the presumed infarcted area which exhibits normal contractility in contrast ventriculographic study[15] Thus at least some of the new Q waves seen postoperatively may be the result of something other than myocardial infarction—and should be included in the list of causes of pseudo infarction Infrequently pseudo infarction is encountered with hyperkalemia[57] or straight back syndrome[11]

Right bundle branch block (references 2 to 16 161 to 172)

The experimental vectorcardiography of right bundle branch look has been studied in humans—catheter induced in the right ventricle postoperatively (after repairs of ventricular septal defects) and in patients whose conduction disorder was intermittent or was induced by premature atrial stimulation[1, 5, 1]

From these observations it can be reasonably stated that right bundle branch block is essentially a distal disorder of conduction leaving unaffected the initial 40 msec of the QRS complexes Beginning at about 60 msec after the E point the QRS loop deviates anteriorly and to the right with the terminal forces exhibiting clustered time dashes due to slower activation in the right side of the septum and the right ventricle[4, 6] Thus it is evident that in right bundle branch block the QRS loops are prolonged in duration (increased number of time dashes) to values of 110 to 170 msec or even longer

The sparing of initial forces indicates that those diagnoses which depend on alterations in the earlier QRS vectors (such as myocardial infarction and even left ventricular hypertrophy) could still be established in the presence of right bundle branch block

Several authorities have suggested abandonment of the term right bundle branch block in favor of right ventricular conduction delay thus eliminating the unsatisfactory term incomplete right bundle branch block which has been used to describe a similar electrocardiographic and vectorcardiographic picture but with a shorter total time duration than 120 msec In the author s experience right ventricular conduction delays with a total duration of less than 120 msec usually exhibit the terminal slowing right and posterior to the E point while in instances with conduction prolongation to 120 msec or greater terminal delay is more commonly anterior and rightwards

The characteristic horizontal plane QRS loop in right bundle branch block is very easy to recognize The initial portions of the loop are very similar to the normal QRS with counterclockwise movement from the E point beginning in an anterior direction and with the major QRS forces oriented to the left and posterior Instead of returning to the E point however the QRS loop continues and inscribes a large appendage anterior and to the right of the E point usually with counterclockwise rotation in the appendage and with clustering of the time dashes[18, 170]

The frontal QRS loop has a normal axis that is an orientation inferior to the X axis and to the left of the E point The initial portion of the QRS loop may be normal in the frontal plane with either clockwise or counterclockwise rotation but the characteristic feature is the terminal appendage which is always oriented to the right but may be inferior or superior to the E point In uncomplicated right bundle branch block the frontal axis is neither markedly superior nor markedly rightwards as is the case when a left divisional block is superimposed[17, 72]

The horizontal plane T loop in right bundle branch block is characteristically left and posterior with clockwise rotation The T loops in right bundle branch block and its variations will be described in a separate section on T loops Occasionally in the acute and experimental varieties of right bundle branch block described above the body of the QRS loop is inscribed completely anterior to the E point and may even exhibit clockwise rotation[96] It is important to realize

sional block[1, 3] However the frontal plane vectorcardiographic loop is quite characteristic and easy to recognize The initial forces are always superior and may be oriented to the left or right The major axis of the loop is distinctly vertical close to the Y axis and terminal slowing oriented to the right is always present as in uncomplicated right bundle branch block

Various configurations of the QRS loop have been described in the horizontal plane with clockwise counterclockwise and figure of eight loops occurring with about equal frequency In the series of Varriale and Kennedy[198] who reported 12 patients with this combination all the horizontal plane loops initial forces were anterior or directly leftwards The horizontal plane loops present terminal rightward anterior conduction delay with clustering of time dashes characteristic of right bundle branch block. Many horizontal loops of patients with combined right bundle branch block and inferior divisional block have very prominent anterior QRS forces unrelated to the presence of dorsal myocardial infarction or of right ventricular hypertrophy Thus this particular combination of divisional blocks again presents the opportunity for overdiagnosis of prominent anterior QRS forces Five of Kennedy and Varriale s patients had well established inferior infarction in addition to their conduction disorders and in two anterior infarction was also present Before the diagnosis of right bundle branch block combined with inferior divisional block is made four other entities must be considered These are right bundle branch block combined with one of the following right ventricular hypertrophy chronic pulmonary disease slender body build or extensive lateral infarction

Ordinary clinical examination is usually sufficient to rule out the first three of these possibilities and in the last abnormally large and prolonged early rightward forces might suggest the correct diagnosis

Obviously right bundle branch block combined with inferior divisional block produces a marked vertical shift in the frontal plane axis while right bundle branch block combined with superior divisional block produces a marked superior shift in the frontal plane axis In some patients with chronic right bundle branch block the associated inferior or superior divisional block may be intermittent and it was from observations of axis shift in such cases that Rosenbaum first deduced logically the concept of a multidivisional conducting system arising from the left bundle branch

Myocardial infarction combined with superior or inferior divisional block (references 2 to 16 199 to 209)

Inferior myocardial infarction combined with superior divisional block results in a characteristic and easy to recognize frontal vectorcardiographic loop[199-201] The inital 25 to 40 msec of the loop reflect the inferior infarction

The generated QRS forces are superior to the E point and rotate to the left along the X axis with the 25 and usually the 30 msec vector superior to the X axis[11, 201] The loop then turns superiorly and changes its rotation from clockwise to counterclockwise so that the bulk of the QRS loop lies superior to the X axis[199-201] Thus while the initial forces reflect the inferior infarction the terminal forces reflect the superior divisional block A frequent electrocardiographic problem is the interpretation of records displaying QS or QRS complexes in leads 2 3 and aV$_F$ When a frontal loop as just described is present combined inferior infarction and superior divisional block is evident[200] However if the frontal loop is markedly superior but exhibits clockwise rotation throughout the diagnosis is inferior infarction probably extensive but without combined superior divisional block[199] As Benchimol has pointed out the combined diagnosis is of great predictive value in assessing possible coronary artery obstruction since inferior infarctions are generally associated with right coronary artery lesions, while the superior division of the left bundle is nourished by the left anterior descending artery[200] Thus when the combined diagnosis is made double coronary vessel disease should be suspected clinically

In other patients with inferior infarction the axis is markedly vertical or even rightwards despite the initial prolongation of superior forces characteristic of inferior infarction[201-203] Here the diagnosis is inferior infarction combined with inferior divisional block This is a combination probably described previously by First and associates[204] as inferior infarction with "peri infarction block In some patients with inferior myocardial infarction injection of contrast material into the right and left coronary arteries successively produces an associated inferior and

opposite picture in the frontal plane.[13, 1] The initial forces are oriented superiorly and usually to the left, and the major QRS vectors are always directed inferiorly and usually to the right.[1, 3, 194] The loop rotation in the frontal plane is practically always clockwise. The late rightward forces observed in the frontal plane, of course, are also apparent in the horizontal plane, which maintains its normal counterclockwise rotation with initial forces inscribed anterior and to the left. It is apparent from this description that the QRS loops in the horizontal and frontal plane of inferior divisional block closely resemble the description of loops in Type C right ventricular hypertrophy as commonly observed in mitral stenosis, emphysema, and cor pulmonale.

Superiorly displaced frontal loops resembling those of superior divisional block may also occur with emphysema. Hyperkalemia may occasionally present with a marked superior or inferior frontal axis which may indeed represent superior or inferior divisional block, respectively, as these changes are reversible with correction of the electrolyte abnormality.[1, 7] A special type of counterclockwise superior frontal loop is commonly seen in patients with endocardial cushion defects.[1, 5] In these cases, the anatomic length of the superior division is prolonged as it courses along the anterior surface of the defect, while the inferior division is much shorter. This discrepancy in length results in sequential rather than simultaneous activation of the myocardium supplied by the superior and inferior divisions, respectively, with a resultant superior counterclockwise frontal loop resembling in every way superior divisional block.

Right bundle branch block combined with superior divisional block (references 2 to 16, 189 to 196)

When right bundle branch block is combined with superior divisional block, the terminal conduction delay oriented to the right and anterior with clustered time dashes is unchanged.[1, 9] However, a marked superior shift in the frontal plane axis occurs with the body of the QRS loop prior to the terminal appendage being inscribed well above the X axis and with counterclockwise rotation—as in the case of uncomplicated superior divisional block. The initial QRS forces are practically always inferior in location and may be inscribed either to the right or to the left.[90]

In the transverse or horizontal plane, two morphologies designated types A and B by Lichstein and associates[1] have been described and confirmed by several other observers.

In the more common type A horizontal loop, the body of the loop is inscribed counterclockwise and to the left with the maximum vector either anterior or posterior. The terminal appendage then follows characteristically oriented to the right and anterior of the E point. In the type B horizontal loop, the sense of rotation is clockwise with the entire QRS loop oriented to the E point.

In several clinical investigations attempts have been made to correlate these type B loops with associated dorsal myocardial infarction or right ventricular hypertrophy, but without significant success, as the majority of such cases lack other stigmata of these conditions. However, the type B loops are associated with a somewhat higher incidence of proven organic heart disease, ventricular hypertrophy, etc.[1]

In the author's view, the type B loops probably represent additional delay in the anterior or midseptal fascicle of the left bundle branch system. Delay in that branch would account for anterior displacement of the QRS loop and for the clockwise rotation observed without invoking additional hypertrophy or infarction. In this type B loop of right bundle branch block combined with superior divisional block, the vectorcardiographer encounters yet another circumstance in which overdiagnosis of prominent anterior forces, in this instance combined with clockwise rotation, may easily lead to mistaken diagnoses of serious organic heart diseases. At least partial confirmation of the concept of anterior conduction delay in the genesis of the type B loop is found in the work of Cohn and colleagues,[8] who demonstrated a variety of ventricular aberrations following stimulated atrial premature beats, some of which exhibited vectorcardiographic loops identical to the type B loop described above in the absence of dorsal infarction or right ventricular hypertrophy and which were intermittent. At slower heart rates the vectorcardiographic loops in these individuals were perfectly normal.

Right bundle branch block combined with inferior divisional block (references 197, 198)

The combination of complete right bundle branch block with inferior divisional block is considerably less frequent than the combination of right bundle branch block with superior divi-

sional block[197, 198] However the frontal plane vectorcardiographic loop is quite characteristic and easy to recognize The initial forces are always superior and may be oriented to the left or right The major axis of the loop is distinctly vertical close to the Y axis and terminal slowing oriented to the right is always present as in uncomplicated right bundle branch block

Various configurations of the QRS loop have been described in the horizontal plane with clock wise counterclockwise and figure of eight loops occurring with about equal frequency In the series of Varriale and Kennedy[198] who reported 12 patients with this combination all the horizontal plane loops initial forces were anterior or directly leftwards *The horizontal plane loops present* terminal rightward anterior conduction delay with clustering of time dashes characteristic of right bundle branch block Many horizontal loops of patients with combined right bundle branch block and inferior divisional block have very prominent anterior QRS forces unrelated to the presence of dorsal myocardial infarction or of right ventricular hypertrophy Thus this particu lar combination of divisional blocks again pre sents the opportunity for overdiagnosis of promi nent anterior QRS forces Five of Kennedy and Varriale s patients had well established inferior infarction in addition to their conduction disor ders and in two anterior infarction was also present Before the diagnosis of right bundle branch block combined with inferior divisional block is made four other entities must be consid ered These are right bundle branch block com bined with one of the following right ventricular hypertrophy chronic pulmonary disease slender body build or extensive lateral infarction

Ordinary clinical examination is usually suffi cient to rule out the first three of these possibili ties and in the last abnormally large and pro longed early rightward forces might suggest the correct diagnosis

Obviously right bundle branch block combined with inferior divisional block produces a marked vertical shift in the frontal plane axis while right bundle branch block combined with superior divi sional block produces a marked superior shift in the frontal plane axis In some patients with chronic right bundle branch block the associated inferior or superior divisional block may be inter mittent and i was from observations of axis shift in such cases that Rosenbaum [7] first deduced logically the concept of a multidivisional con ducting system arising from the left bundle branch

Myocardial infarction combined with superior or inferior divisional block (references 2 to 16 199 to 209)

Inferior myocardial infarction combined with superior divisional block results in a characteris- tic and easy to recognize frontal vectorcardio- graphic loop[2] [1] The inital 25 to 40 msec of the loop reflect the inferior infarction

The generated QRS forces are superior to the E point and rotate to the left along the X axis with the 25 and usually the 30 msec vector superior to the X axis[11] [1] The loop then turns superiorly and changes its rotation from clockwise to coun terclockwise so that the bulk of the QRS loop lies superior to the X axis[199] [01] Thus while the initial forces reflect the inferior infarction the terminal forces reflect the superior divisional block A frequent electrocardiographic problem is the interpretation of records displaying QS or QRS complexes in leads 2 3 and aV_F When a frontal loop as just described is present combined infe- rior infarction and superior divisional block is evident [9] However if the frontal loop is marked ly superior but exhibits clockwise rotation throughout the diagnosis is inferior infarction probably extensive but without combined superior divisional block[199] As Benchimol has pointed out the combined diagnosis is of great predictive value in assessing possible coronary artery obstruction since inferior infarctions are generally associated with right coronary artery lesions while the superior division of the left bundle is nourished by the left anterior descend ing artery [00] Thus when the combined diagnosis is made double coronary vessel disease should be suspected clinically

In other patients with inferior infarction the axis is markedly vertical or even rightwards despite the initial prolongation of superior forces characteristic of inferior infarction[203-205] Here the diagnosis is inferior infarction combined with inferior divisional block This is a combination probably described previously by First and asso- ciates [6] as inferior infarction with peri infarc tion block In some patients with inferior myo- cardial infarction[17] [1] [9] injection of contrast material into the right and left coronary arteries successively produces an associated inferior and

then superior divisional block on a temporary basis The combination of inferior infarction with inferior divisional block produced by such experiments is quite similar to loops described as inferior infarction with peri infarction block

In contrast to the above anterolateral infarction accompanied by superior divisional block would result in a frontal plane loop characterized by abnormally prolonged and large initial rightward forces (lateral infarction) followed by a continuation of the loop superiorly and counterclockwise in the left superior quadrant of the frontal plane—with these terminal forces characteristic of superior divisional block Thus the criteria for so called peri infarction block would be met with the initial vectors opposite the terminal vectors Experimentally patients with anterolateral infarction may have a picture closely resembling peri infarction block superimposed by selective injection of the left coronary artery

Although the author believes that most cases described as peri infarction block probably represent infarction combined with a divisional block it still remains possible that in some instances the conduction disturbance is indeed peripheral and is localized in the ischemic tissue around the necrotic zone of the infarction [08]

Since the diagnoses of superior or inferior divisional block are made from the frontal plane vectorcardiogram which does not display anterior/posterior forces the diagnosis of associated anterior infarction rests with the disposition of the initial vectors in the horizontal reference plane

Thus characteristic deformities as described in the section on anterior infarction will co exist with typical terminal frontal loop abnormalities characteristic of either superior or inferior divisional block as described above One special variety of infarction combined with divisional block deserves particular mention This is true dorsal infarction combined with inferior divisional block Here in the transverse plane the initial half of the loop is displaced anteriorly to the left anterior quadrant of the horizontal plane while the major axis in the frontal plane is oriented inferiorly with clockwise rotation This vectorcardiographic QRS loop obviously closely resembles Type B or Type C right ventricular hypertrophy but in fact may on occasion really represent a combination of inferior divisional block with anterior conduction delay The reader is reminded that anatomical studies reveal that the anterior fascicle of the left bundle branch frequently arises from the inferior division Thus fibrosis or scarring of that division proximal to the bifurcation into the inferior and midseptal divisions could well account for this last vectorcardiographic picture described

The entire subject of myocardial infarction complicated by intraventricular conduction disturbances is beautifully outlined in program form by Lemberg and Castellanos in their book Vectorcardiography

In that text and in at least one publication [09] Castellanos advances the concept of intra infarction block. This diagnosis is to be suspected when the Q waves produced by an infarction or the corresponding portion of the vectorcardiographic loop exhibit slurring or notching lasting 20 msec. The genesis of this abnormality may well be islands of living myocardium within the infarcted zone These islands by contributing relatively normal QRS voltages during the subtraction effect of the infarcted tissue surrounding result in an interruption of the usually smooth initial defect resulting from the infarction [09] This is an interesting and valuable conception and may well explain the observed phenomenon which is encountered occasionally in vectorcardiographic tracings.

Right bundle branch block combined with myocardial infarction (references 2 to 16 199 to 209)

When right bundle branch block is combined with inferior wall infarction the diagnosis is quite easy by vectorcardiogram The reason is simple enough The right bundle branch block, which displaces the terminal QRS forces right and anteriorly as previously described is not only a distal phenomenon in the QRS loop but is most evident in the horizontal reference plane Although the terminal rightward delay is evident in the frontal plane the initial 25 to 40 msec of the QRS loop are not affected and still will reveal the characteristic abnormality of myocardial infarction of the inferior wall

Lateral myocardial infarction which is generally diagnosed on the basis of a prolongation of initial rightward forces beyond the normal value of approximately 25 msec is likewise evident in both the horizontal and frontal references even

cardiogram exhibiting left bundle branch block, accurate localization is possible in about half the cases although many remaining patients do indeed have infarctions but in unexpected areas Goldman and Pipberger[11] have identified other criteria useful in recognizing infarction in the presence of left bundle branch block An absence of an anterior ST junctional displacement was indicative of infarction at the 95th percentile level and a T magnitude in the horizontal plane of less than 0 2 millivolts was also indicative of infarction at the 95th percentile level Goldman and Pipberger[11] also confirmed the importance of initial rightward QRS forces or prominent anteri or forces as criteria for myocardial infarction in the presence of left bundle branch block In the series of Goldman and Pipberger the total iden tification rate was 50% with 14% false positives These results were approximately equal to the diagnostic power of the vectorcardiogram in iden tifying myocardial infarction in the presence of right bundle branch block These autopsy con firmed VCG patterns for myocardial infarction in the presence of left bundle branch block resemble very closely the vectorcardiograms produced by Bisteni and colleagues [212] who used phenol injec tions to induce areas of necrosis in experimental animals with previously induced left bundle branch block The above data are rather convinc ing in establishing the value of vectorcardiogra phy in the assessment of patients presenting with left bundle branch block and in whom coronary artery disease with infarction or myocardial fibrosis is suspected clinically

Incomplete left bundle branch block

In so called incomplete left bundle branch block the total duration of the QRS loops is between 100 and 120 msec In general these loops resemble those of left bundle branch block except that the duration is shorter In the characteristic case the initial forced are oriented to the left and anterior in the horizontal plane which may retain its u ual counterclockwise rotation but occasion ally is figure of eight with the proximal section coun erclockwise and the distal section clockwise

The frontal loop is oriented close to the X axis but not above it with characteristic counter clockwise rotation Scalar electrocardiographic features of left ventricular hypertrophy are often present in these cases

Right ventricular hypertrophy with left bundle branch block (reference 223)

A little known application of the vectorcardio gram in left bundle branch block is the diagnosis of right ventricular hypertrophy Chou and Helm[223] described five patients with unequivocal right ventricular hypertrophy whose vectorcar diograms could easily be recognized as typical o left bundle branch block The contour of th horizontal loops the mid and terminal slowing and the clockwise rotation were all characteristic The QRS loops were prolonged and the initia QRS forces were oriented to the left and inferior ly However in two ways these loops differe from the typical uncomplicated stereotype of lef bundle branch block These were the rightwar displacement of the body of the QRS loop and th leftward orientation of the ST vector and T loop

Although as described above rightward dis placement of QRS may be seen in left bundl branch block complicated by myocardial infarc tion there are distinct differences from Chou and Helm s patients[2 3] with right ventricular hyper trophy When marked rightward deviation i present secondary to infarction in left bundl branch block the displacement is initial or termi nal with the bulk of the loop still oriented to th left and posteriorly Further when early force are displaced to the right in myocardial infarctio complicated by left bundle branch block th rotation is generally rightward and clockwis *about the E point* whereas in left bundle branch block complicated by right ventricular hypertro phy the early rotation about the E point i counterclockwise The cardiologist is encourage to become familiar with the normal stereotype o left bundle branch block and with the variation described from which myocardial infarct on o right ventricular hypertrophy may be suspected In the author s opinion patients with left bundl branch block present frequent opportunities fo additional diagnosis from the vectorcardiogram and the test should be employed frequently i these individuals

Right bundle branch block combined with righ ventricular hypertrophy (references 2 to 16 224 to 228)

Baydar and colleagues presented a classifica tion of right bundle branch block in relation t right ventricular hypertrophy and chronic pulmo

diagnosis beyond the conduction disorder is ble However a surprising amount of infor is available from careful examination of loops in left bundle branch [1] Indeed Goldman and Pipberger have emonstrated that vectorcardiographic criteria e about as accurate in identifying the presence of myocardial infarction accompanying left bun e branch block as in the case of right bundle branch block

In order to use the vectorcardiogram properly in left bundle branch block the cardiologist must become familiar with the stereotype of left bundle branch block as it is encountered in the absence of cardiac abnormality or as produced mentally [1] Under such circumstances a rather typical picture is seen The initial QRS forces are oriented to the left and anteriorly and always rotate in a counterclockwise manner with a duration of anterior forces about 10 to 20 msec [1] The second vectorial movement as out lined by Scott [11] is directed leftward posteriorly and inferiorly attributed by Bisteni and col leagues [1] and also by Wallace and associates to right to left activation of the interventricular septum At about 50 msec the third vector appears This is directed leftward superior and posterior and exhibits slurring and clustering of time dashes Here the rotation changes from counterclockwise to clockwise and this sense of rotation persists for the duration of the QRS loop as seen in the horizontal plane The last vector the fourth which corresponds to the returning limb or the afferent portion of the QRS loop is oriented posterior and left and is attributed to activation of the left ventricular free wall The closest spacing of time dashes is during the inscription of the third vector described above

In the frontal reference plane the initial forces are oriented to the left and inferiorly The loop is inscribed in a counterclockwise manner usually inferior to the X axis although the terminal forces may be inscribed above the X axis The T loop in the horizontal plane is oriented to the right and anterior and is usually counterclockwise while in the frontal plane it is right and inferior and also counterclockwise [m] Neuman and colleagues and Pietras and co workers have evaluated various criteria for myocardial infarction in patients with left bundle branch block followed to necropsy and subjected to detailed postmortem examination of the heart In all six variations from the typical stereotype of left bundle branch block were considered and evaluated as infarction criteria Clockwise rotation of the initial forces of the QRS loop about the E point in the horizontal plane was evaluated as a criterion for septal infarction Of 13 such patients all had myocardial infarction or fibrotic areas six of which were concentrated in the ventricular septum The remaining patients had infarction or fibrosis in other myocardial areas A posterior position of the 01 sec vector as seen in the horizontal plane was tested as a criterion for anterior apical infarc tion Of nine such patients four had infarction or fibrosis of the anterior wall and the remaining five had fibrosis or infarction but located in other areas

Rightward displacement of the afferent limb (but not crossing to the right of the E point) was evaluated as a criterion for lateral infarction Six patients presented such vectorcardiograms and five had either infarction or fibrosis of the lateral wall The remaining patient had a septal infarct

Displacement of the afferent limb of the QRS to a point greater than 0 05 millivolts to the right of the E point was evaluated as a criterion of anterolateral infarction Of 14 patients with this abnormality seven had infarction or fibrosis in the anterior and lateral areas six patients had infarction or fibrosis in other areas and one patient had left ventricular hypertrophy An anterior position of the 02 5 sec vector was evaluated as a criterion for true posterior infarc tion Seven patients met this criterion of whom five indeed had posterior infarctions at necropsy The remaining patients had infarction or fibrosis in other areas A superior frontal mean axis (between −30 and −180 degrees) was evaluated as a criterion for myocardial infarction Of 21 patients with such a superior axis 14 had infarc tions demonstrated at autopsy In the largest group (ten patients) the infarction was dorsal in location All the remaining patients had infarc tion or fibrosis in other areas and several had ventricular hypertrophy as well In comparing the performance of vectorcardiographic versus electrocardiographic diagnosis it was very evi dent that the vectorcardiogram was quite superior in the diagnosis of infarction in the present of left bundle branch block [-1] However the authors of these studies point out that when criteria for infarction are met by a vector

ular system an initial delay is noted in the QRS loop which is directed away from the point of origin of the ectopic beat In this respect, such loops are similar to those generated by pacemaker stimuli or via AV bypass tracts in the pre excitation syndromes [31]

After the initial delay, which varies in duration from 20 to 40 msec rapid conduction may follow usually oriented in the same direction as the initial forces This probably represents entrance of the activation wave into an adjacent fascicle A change in direction then commonly occurs as myocardium not activated by the initial fascicle depolarizes and this in turn is followed by slow activation of the ventricle opposite the site of initial ectopy When the ventricular point of origin of the premature beat is not near a segment of the fascicular system the initial delay may not be followed by as many directional changes until activation of the opposite ventricle occurs [9]

Probably the most importance feature of vectorcardiography in ectopic ventricular beats is the detection of the initial slowing which serves to locate the point of origin of the ectopic beat [31] As has been pointed out by several authors inspection of the scalar ECG or even of orthogonal leads may not be sufficient in localizing this initial delay which may be apparent only as a step in the VCG loop [2 9 3 23]

Talbot and associates have located the initial forces in vectricular ectopic vectorcardiograms using the 360 degree planar reference system for the frontal and horizontal planes It is evident from their data that these initial slow forces may be located anywhere indicating a large variety of possible ventricular sites of origin in either ventricle The majority of initial delays were located to the left of the E point in the frontal plane mostly inferior and either anterior or posterior to the E point when considered in the horizontal plane The rotational characteristics of the QRS loops resulting from ventricular ectopy were highly variable Clockwise rotation in the horizontal plane was a common finding

The QRS loops resulting from pacemaker stimulation are similar in many ways to the vectorcardiographic loops arising from spontaneous ventricular ectopy The entire QRS loop is prolonged in duration owing to conduction delay in the ventricle opposite the one stimulated Thus with right *ventricular stimulation the major axis of* the induced QRS loop is leftward and the opposite situation prevails with left ventricular stimulation [219 2 0] Pacemaker stimulation inferior in a ventricle will result in a superiorly directed QRS loop while electrodes placed in the outflow tract will result in inferiorly placed loops Similar considerations apply to anterior and posterior direction—with anterior positioning resulting in posterior loops Castellanos and co workers have succeeded in reproducing spontaneously occuring VPC configuration by selective stimulation of various portions of the right ventricle or left ventricle by placement of the pacing electrode at the right ventricular apex in the coronary sinus or within the middle cardiac vein

An invariable feature of pacemaker vectorcardiographic loops is an initial delay entirely similar to that seen frequently in ventricular ectopy This initial delay is most frequently oriented inferior and left about half are anterior and half are posterior [39] The body of the QRS loop may be clockwise counterclockwise or figure of eight in all three reference planes with the commonest finding a figure of eight loop in both horizontal and frontal planes [31 33 241] Since infarction induces changes in the vectorcardiographic loops of left bundle branch block (which right ventricular paced loops resemble) attention has been paid to similar changes in the pacemaker VCG loops of patients with underlying myocardial infarction [3 237 41] Not surprisingly the induced QRS loops are indeed modified and resemble very closely the variations produced in spontaneous left bundle branch block by myocardial infarction as occuring under natural or experimentally induced conditions [1] With inferior myocardial infarction the right ventricular paced vectorcardiographic loop is oriented superiorly with initial delay also oriented superiorly and with clockwise rotation of the frontal plane loop [235 241] In true posterior infarction the initial delay was oriented markedly left and anterior with counterclockwise rotation of the induced horizontal loop This picture according to Zoneraich and Zoneraich [23] *is unique* With infarction of the anteroseptal areas the initial QRS vectors were oriented right and posterior with clockwise rotation of the horizontal plane loop—thus closely resembling the alterations produced in naturally occuring left bundle branch block complicated by anteroseptal infarction [19 0] The stimulus artifacts from unipolar catheters are about ten times larger than those produced with *bipolar*

ary disease based upon the horizontal plane on of the afferent (returning) limb of the QRS loop Thus in patients with an afferent limb r to the E point no right ventricular hypertrophy or pulmonary disease was expected In a second group the afferent limb was anterior the E point but the loop rotation remained clockwise Here an increased incidence of ventricular hypertrophy and chronic pulmonary disease was encountered In the third group only was the afferent limb anterior to the E point but the entire loop exhibited a clockwise Here the incidence of right ventricular y or chronic pulmonary disease was the highest

In a recent re evaluation of these criteria Fedor and colleagues[226] confirmed an increasing idence of cardiac failure or severe pulmonary as vectorcardiograms were arranged ig to these three groups designated as Types I II and III Although Fedor and associates concluded that the Type III variety was a reliable guide to cardiac failure or severe pulmonary disease—and indeed even to pulmonary hypertension their data indicate that five of 31 patients falling into this Type III group (16%) had only insignificant cardiac or pulmonary disease The reader is here referred to prior discussion of right bundle branch blocks combined with divisional block induced by atrial premature stimulation This commonly results in transient aberration and vectorcardiographic loops identical with the Type III variety as commonly encountered clinically and associated with chronic pulmonary disease

Chou and associates studied children with right ventricular hypertrophy determined at cardiac catheterization who had both pre and post operative vectorcardiograms with the latter exhibiting a new right bundle branch block These patients without question reflected in their second vectorcardiogram the combination of right bundle branch block associated with right ventricular hypertrophy Chou and colleagues were unable to confirm that clockwise rotation in the horizontal plane was a reliable indicator for such right ventricular hypertrophy as the sense of rotation changed in 50% of the operative patients who developed postoperative right bundle branch block However these authors did offer three criteria which were useful in children[22] These were a maximum QRS vector directed to the right of 65 degrees in either the horizontal or frontal plane a maximum rightward vector exceeding the normal value for age (generally a value greater than 1 0 millivolts) and lastly an abnormal ratio of leftward to rightward QRS forces (RX/SX) the critical value being 0 91 in the oldest age group studied (ages 10 to 16 years)

The T loops in right ventricular hypertrophy with or without bundle branch block are oriented to the left with clockwise rotation in the horizontal plane and are usually located posterior to the E point[26] Additional discussion of the T loops in right bundle branch block and in RVH is to be found in a subsequent section devoted entirely to T loops Clearly the vectorcardiographer attempting the diagnosis of RVH in the presence of a right bundle branch block on the basis of a prominently anterior and clockwise horizontal loop is liable to make mistakes A very similar picture as described above has been found with right bundle branch block combined with superior divisional block or combined with true dorsal infarction Conduction delay in the anterior fascicle may also play a role especially when another divisional block is already present However when even a modicum of clinical information is available the vectorcardiographic diagnosis may be pronounced with more authority

The vectorcardiography of premature ventricular or pacemaker induced complexes (references 229 to 242)

Despite the technical difficulty in obtaining vectorcardiograms of ventricular premature contractions several authors have accumulated a sizable series of such beats [30 1 33] Although several varieties of loop disturbances have been described they are readily understandble in the light of published information on the vectorcardiography of bundle branch and fascicular blocks

For example about twenty % of ventricular premature beats exhibit vectorcardiograms which are indistinguishable from uncomplicated right or left bundle branch block.[2 9] It may be presumed that the beats resembling right bundle branch block arise in the left main bundle branch while those resembling left bundle branch block arise in the right main bundle [1 2] The large majority of ventricular ectopic beats however are considerably more complex but nevertheless understandable When the ectopic focus is outside the fascic

direction or rotation abnormal width in addition is of little value in diagnosis as all presently described T loop abnormalities be they secondary to conduction delays hypertrophy or ischemia have the capacity to widen the T loop

Scalar electrocardiographers have long been used to the term primary or secondary T wave abnormalities and a parallel exists in vectorcardiography The secondary T loop abnormalities may be attributed to alterations in the repolarization sequence as seen in right or left ventricular hypertrophy and right or left ventricular conduction disorders[219, 231, 2, 6, 59, 61] Primary repolarization abnormalities are attributed to local disorders of recovery, usually in segmental ischemic zones of the left or right ventricles

The basic change in recovery physiology in an ischemic zone is a prolongation of action potential Thus the last portion of the myocardium to generate recovery potentials is the ischemic zone and owing to the return of the unaffected myocardium to resting potential by that time the observed T wave and T loop must be directed away from the area of ischemia Smith and colleagues[17] noted marked shifts in the direction of the T loops during right or left coronary artery injection respectively with contrast material Right coronary artery injection producing transient ischemia of the inferior wall resulted in a leftward and superior shift of the T loop resembling the direction observed in clinical inferior infarction with a surrounding ischemic zone In contrast left coronary injections caused a shift of the T loop to the right and inferior entirely similar to changes observed with lateral myocardial ischemia These changes were of course transient and reversible

Several authors have described the T loop abnormalities seen in coronary artery and other myocardial diseases [5, 6] In general ischemic T loops change in direction as noted above with their long axis directed away from the ischemic zone In addition the length/width ratio ch nges so that the loops are characteristicly ov ic with the most terminal portions of the T loo pposite the area of slow repolarization T a rather circular loop in which the early ba t forces may be anterior with the terminal posterior is commonly seen with anterio dial ischemia This type of loop results lus minus T wave in the precordial lead imilar considerations apply to inferior, lateral and dorsal ischemia. In this latter condition since the T loop is normally anterior and left the development of dorsal ischemia may shift the T to a directly anterior position However because of lateral ischemia which is often associated the most terminal T forces are oriented the most medially resulting in a change in rotation of the horizontal T loop from counterclockwise to clockwise In a T loop of normal width clockwise rotation in the left anterior quadrant is almost never seen in normals[2, 252] In the presence of clinically suspected coronary disease such a vectorcardiographic observation should be taken as evidence favoring dorso lateral ischemia Vectorcardiographic T loops exhibit another interesting characteristic in many cases The terminal T forces may exhibit slowing so that the entire loop is evenly inscribed, corresponding to the symmetrical T wave commonly encountered in scalar electrocardiography and recognized as characteristic of myocardial ischemia[2, 3, 5]

An excellent programmed introduction to the vectorcardiography of T loops was presented by Castellanos and colleagues It should be emphasized at this point that the vectorcardiographer interpreting an ischemic T loop is really considering three repolarization phenomena all simultaneous with the observed T loop the resultant In a case with a localized area of left ventricular ischemia the balance of the left ventricle may well be generating perfectly normal T potentials and a normal T loop The right ventricle may similarly be generating a normal right ventricular T loop Thus the observed T loop represents the summation of the normal left and right ventricular repolarization with the ischemic repolarization added

The secondary T loop abnormalities observed in left ventricular hypertrophy and the left ventricular conduction delays (left bundle branch block right ventricular pacing and ventricular premature beats arising in the right ventricle) are all very similar Since these conditions in the pure form do not affect the right ventricle the T loop generated by the right ventricle is in its usual position—anterior However the hypertrophy or conduction disorder affecting the left ventricle alters the recovery sequence so that the resulting T loop is directed opposite the observed QRS and becomes located to the right and anterior of the E point The right anterior T loop

timulation owing to the much greater distance etween the negative electrode and the pulse nerator in the case of a unipolar pacemakers compared to the approximately ten mm distance tween negative and positive poles with bipolar atheters [3] Therefore the stimulus artifact with unipolar pacemakers is directed from the catheter n to the anatomic location of the battery pack ver it has been implanted On the other hand with transvenous bipolar catheters placed the apex of the right ventricle the vector presenting the stimulus artifact is usually to the right and superior Much greater ariation is possible in the case of left ventricular ters which may be placed anywhere on the ventricular surface A change in axis of the stimulus artifact from a bipolar pacing catheter may result from wire breakage as the stimulation changes from bipolar to unipolar with the artifact axis now depending upon the location of the battery pack and the site of ventricular contact proximal to the break

Pacemaker vectorcardiography and the vectorcardiography of ectopic ventricular beats have provided a fascinating confirmation of the information so laboriously accumulated concerning bundle branch blocks fascicular blocks the preexcitation syndrome and their combinations with myocardial infarction

Zoneraich and colleagues [2] have correlated the electrocardiographic and vectorcardiographic findings resulting from right ventricular pacing with echocardiography of the intraventricular septum A posterior twitch of the left side of the *septum entirely similar to that described in* spontaneous left bundle branch block has been observed with pacemaker stimulation—except that this twitch occurs about 30 msec later (probably owing to the initial delay occuring with pacemaker excitation of the heart) No doubt future studies will extend these observations in which echocardiography and vectorcardiography are correlated

Vectorcardiography of the T loops (references 2 to 16 106 243 to 269)

Just as the QRS loops at any moment in time represent the sum of all electrical activity of the entire heart (right and left ventricles) so does the T loop represent the summation of recovery potentials in both ventricles simultaneously [2] That the right ventricle contributes to the T loop should be no surprise to any cardiologist familiar with the obvious T abnormalities seen in conditions such as right bundle branch block and right ventricular hypertrophy Obviously the right ventricle is capable of generating very large recovery potentials which may indeed dominate the observed T loop

Similarly in the normal the observed T loop is the resultant of a leftwards T loop generated by the left ventricle added to a directly anterior T loop generated by the right ventricle [2 3 6 17] It is the sum of these two separate repolarization phenomena that results in the normally observed T loop directed to the left inferiorly and anteriorly—thus making a rather wide angle in the horizontal plane with the left and posterior QRS loop

The electrophysiology of repolarization has been presented by several authors [4] as has the morphology of the normal vectorcardiographic T loop [2 5] In addition to the directional characteristics mentioned above the normal T loop rotates in a counterclockwise manner in the horizontal plane and is either narrow or clockwise in the frontal plane Some normal T loops are so elongated and slender that rotational description has little meaning Indeed some authors recommend that no description of rotation be made when the length with ratio of a T loop in any plane exceeds 10 to 1 Ordinarily the early portions of the T loop are written more slowly than the terminal portion accounting for the asymmetric T wave seen in surface scalar recordings [2 2 5] Thus several characteristics *of the normal may be altered by changed physiol*ogy or disease states—that is the direction sense of rotation the length/width ratio and the speed of inscription

Chou and associates have emphasized the spatial length/width ratio in the normal and determined an upper limit of 1 6 This is calculated by dividing the maximum length in any plane by the maximum width in any plane Occasionally the only abnormality found in a vectorcardiographic record may be an alteration in the length/width ratio such that the loop becomes ovoid with a ratio less than 1 6 In the absence of drugs such as digitalis which may cause a similar alteration such a reduction in the length/width ratio should call attention to the possibility of organic heart disease When other T loop abnormalities are present such as abnormal

the T loop persists but the sense of rotation changes from counterclockwise to clockwise in the horizontal plane and the T loop shifts to a posterior leftward position again with an open QRS loop Isaacs and colleagues [3, 4] recommend simultaneous recording of the Frank XYX leads as a useful monitoring technique in exercise stress testing Although they recorded the vectorcardiographic loops simultaneously with exercise the use of magnetic tape recordings would permit a later generation of loops and the use of signal averaging as well [10] Rautaharju and co workers [1] have subjected P ST and T voltages obtained using the Frank lead system during exercise to computer analysis Bizarro and associates recently reported the correlations of various vectorcardiographic criteria with myocardial scarring determined at autopsy Surprisingly the most sensitive criteria found related to T wave voltage in the X Y and Z axes It seems possible therefore that the entire question of specificity of vectorcardiographic T loop criteria should be re explored

Vectorcardiography of the P loop (references 2 to 16 269 to 289)

The technical problems that complicate P loop study arise from the small amplitude of the voltages generated by atrial depolarization necessitating extremely high gain for proper analysis Standardization of one millivolt equal to 20 or 40 cm have been commonly used and even higher sensitivities are possible Several different techniques have been used in order to eliminate overlying portions of the T or QRS loops These techniques include gating in which only the desired portion of the cardiac cycle in this case the P wave is recorded recording on tape followed by averaging by computer and then followed by gating or the technique of examining running or timed loops in which the oscilloscopic beam moves from left to right while the loops are being inscribed Using these technologies as well as simple high quality still loop vectorcardiography a good deal of information has been accumulated about the vectorcardiography of the P complex

Two distinct components of the P loops may be observed which in the normal person are distinctly different in magnitude and direction The initial right atrial component is directed to the left and anterior[l] [...]le the left atrial component occurs later [...] directed left and posteri-orly [2, 2, 4, 6] When the Frank electrode system is used the maximum P vector in the frontal plane is oriented between +30 and +90 degrees (inferior and left) while the maximum vector in the horizontal plane is oriented between −4[...] a[nd] −20 degrees (left and posterior) The magnitude of the maximum horizontal vector of the P loop [is] less than 0 12 millivolts Criteria have been proposed by several workers for the identification of right or left atrial overload The term overload seems preferable at this time to either hypertrophy or dilatation as changes in intra atrial pressure or size may result in identical P loop abnormalities as observed in true hypertrophy (increased atrial wall thickness) [2, 3] Indeed the term overload may itself be too restrictive a[s] intra atrial conduction disorders which will al[so] be discussed may produce P loops closely resembling those observed in left atrial overload In right atrial overload the horizontal P loop shifts to a distinctly left anterior position and to a more vertical position in the frontal reference plane [1, 2, 3] However the duration of the P loop does not increase and therefore remains less than 100 msec in all reference planes The maximum vector in the horizontal plane may be found between +6 and +90 degrees (the left anterior quadrant of the horizontal plane) and in the frontal plane between +50 and +120 degrees (inferior and often rightwards) The magnitude of the maximum anterior deflection exceeds 0 1 millivolts and the ratio of posterior to anterior P loop forces is usually less than one averaging 0 [...] in the experience of Benchimol and associates [6] The P loop rotation in right atrial overload is characteristically counterclockwise in both the frontal and horizontal reference planes The magnitude of the major P vector in the frontal plane is increased and equals or exceeds 0 2 millivolts

Left atrial overload In general although the magnitude of the major anterior P vector remains unchanged from normal (mean value 0 04 millivolts) the magnitude of the posterior P vector distinctly increases exceeding the normal mean value of 0 12 millivolts [7] Further the ratio of posterior to anterior P voltage increases and exceeds 2 The maximum horizontal vector is located between −10 and −90 degrees (left and posterior) while the maximum P frontal vector is located between +60 and −10 degrees (distinctly less inferior than patients with right atrial overload) A figure of eight rotation is common in the

. i secondary to the left ventricular disorders is characteristicly counterclockwise in ... horizontal reference plane[106] Controversy ... exists about the diagnostic significance of a ...se horizontal T loop located in the right anterior quadrant of the horizontal plane in the presence of left ventricular hypertrophy or a left ...ntricular conduction delay[106] Although originally believed to represent coronary artery dis... in addition to the secondary T loop abnor... sufficient evidence has been presented ... arteriography of such patients to indi... that uncomplicated left ventricular hyper... especially with a rather rightward hori... T loop may result in a clockwise rotation of the T in the absence of significant coronary obstruction[2,9] However in the presence of left bundle branch block such rotation probably does ...icate that in addition to the secondary T loop ...ty attributable to the conduction disor... an additional ischemic zone exists[96] In that ...circ...ce three simultaneous T phenomena would again be responsible—that is the normal right ventricular T the secondary left ventricular T and an ischemic left ventricular T

Somewhat similar but occasionally more complicated considerations apply to secondary changes in the T loop generated by the right ventricle[59, 2] Here in the presence of severe right ventricular hypertrophy or right ventricular conduction delays (right bundle branch block left ventricular pacing or ectopic beats arising from the left ventricle) the sequence of recovery is altered in the right ventricle such that the observed T loop is located in the left posterior quadrant of the horizontal plane and typically with clockwise rotation As might be expected from this comment there is no observable difference between the T loop in right ventricular hypertrophy and the T loop in right bundle branch block

Rubler and associates[5] did note that in right bundle branch block complicating clinically established right ventricular hypertrophy the T loop tended to be more posterior than in uncomplicated right bundle branch block The rotation however remains clockwise most commonly and the length/width ratio is often abnormal in both conditions

Obviously if the vectorcardiographer confronts a QRS loop characteristic of right bundle branch block but with a T loop oriented to the right and anterior or posterior a left ventricular abnormality complicating the right bundle branch block must be considered Associated severe left ventricular hypertrophy could be responsible or an ischemic zone in the left ventricle

Uniformity of inscription of such a T loop as well as its location helps to identify ischemia as the cause of the unexpected location of the T loop[4]

The T loop abnormalities which accompany divisional block have not been well worked out In many cases the T loops remain entirely normal However in some examples observed personally or published in atlases with superior divisional block the T loop has all the characteristics of the secondary T loop abnormality observed with left ventricular hypertrophy or left bundle branch block

In some cases of anterior conduction delay the T loops are perfectly normal while in others they assume a posterior position

Just as myocardial ischemia in a single zone may alter the direction shape and rotation of a T loop already influenced by hypertrophy or conduction delay several coexisting ischemic zones may modify one another Thus inferior ischemia combined with lateral ischemia characteristically displaces the T loop right and superior The sense of rotation varies with the terminal T forces directed away from the most ischemic area

T loops should be recorded at moderate high amplification and with gating circuits when possible to remove overlapping segments of QRS and T A useful technique is to alter the interval between time dashes during the T loop recording so that 10 msec separates each dash rather than 2 or 2 5 msec This results in a more readily appreciated sense of rotation

T loop abnormalities after exercise have been reported[26, 6, 3] and correspond quite closely to the ST T abnormalities found in abnormal stress testing Isaacs and colleagues[3, 6] have correlated three different T loop patterns with the three characteristic ST responses to exercise ST junctional depression with an upsloping ST segment has been correlated with an elongated horizontal T loop which remains open at its termination When the ST segment is depressed and isoelectric a wide ovoid horseshoe shape T loop is seen again with an open QRS loop In the most severely abnormal response downsloping ST segment depression the horseshoe shape of

tion delay and the vectorial orientation of these initial forces is directed away from the point of origin of the ectopy, or from the insertion of the bypass tract in the case of W P W

Classifications of W P W by vectorcardiography have described two basic orientations of the initial conduction delay which has a duration varying from 20 to 70 msec Delays oriented anteriorly were designated as Type A and presumably originated from early activation of the posterobasal wall of the left ventricle Type B resulting from early activation of the right ventricular free wall produced delta vectors directed to the left[2 0 2]

In either of these varieties the initial delay could be oriented in a marked superior direction thus mimicking inferior wall infarction[2V1 2] In addition the Type B delta vector if oriented posteriorly would mimic anterior infarction and the Type A QRS loop oriented largely to the left and anterior of the E point could mimic dorsal infarction or right ventricular hypertrophy

More recently[6] the above classification has been expanded Castellanos and co workers[7 9] have recommended that the right ventricular entrances be subdivided into posterior and anterior types The anterior entrance type in Type B exhibits a delta vector directed to the left and posterior while in the posterior entrance type the delta vector is directed to the left and slightly anterior to the X axis In contrast the Type A delta vector is markedly anterior resulting in positive delta and QRS complexes in Leads V_1 and V_2 of the scalar electrocardiogram Tonkin and associates made the important observation that all septal bypass tracts produced a superior 10 msec vector in the frontal plane while all free wall bypass tracts resulted in inferiorly oriented 10 msec vectors Thus determination of the spatial orientation of the initial conduction delay in W P W serves not only to identify the left or right ventricle as the site of entrance but attention to the frontal plane axis may separate free wall from septal bypass tracts Such identification has important surgical implications

Following the initial delay of the delta vector activation of the ventricular masses occurs as a fusion complex between the activation wave generated from the bypass site entrance and the normal activation via the His Purkinje system[51 56] If the activation through the normal conducting system dominates the QRS loop after the delta vector may be largely normal

However if conduction through the bypass trac dominates the conduction through the AV nod and His Purkinje system is delayed varyin degrees of fusion complexes occur producing th electrocardiographic concertina effect described by Portillo[3 1] If activation occurs entire through the bypass tract conduction delay evident throughout the entire QRS loop whi becomes greatly prolonged In the case of Type pre excitation the terminal delay will be orient to the right but usually posterior and does n resemble the common variety of right bund branch block in which the terminal delay oriented to the right and anterior Similarly Type B with pure bypass tract activation of t ventricles conduction delay will be eviden throughout a loop oriented to the left and posterior and which will superficially resemble left bundle branch block[4 97]

An excellent programmed presentation of electrocardiography and vectorcardiography in the W P W syndrome with and without complicating bundle branch blocks was presented by Castellanos and co workers[7] An especially interesting problem is presented by the combination of pre excitation with bundle branch block[4] This is a distinctly different phenomenon from the vectorcardiogram produced by complexes representing total excitation via the bypass tract[2 901] In Type A W P W with early excitation of the left ventricle, a coexistent right bundle branch block is perfectly possible Several patients with early excitation of the left ventricle and coexistent right bundle branch block have been reported, and in others the possibility of this combination was established by artificial catheter induced right bundle branch block[3] In contrast to the loops resulting from total excitation via a left sided bypass the loops of left sided bypass with right bundle branch block display a distinct right anterior terminal appendage as in the usual forms of right bundle branch block described in an earlier section

Of great theoretical interest are those cases in which bundle branch block appears to exist in the same ventricle exhibiting the pre excitation A reasonable explanation seems to exist for Type B W P W of the posterior entrance type with coexistent right bundle branch block Here it seems possible that the posterior entrance leads to activation of the left ventricle via the fascicular system prior to activation of the right ventricle which in turn is aberrant because of the right

horizontal plane with a decrease in duration of the anterior P forces and an X axis intercept (crossing point from anterior to posterior) distinctly less than in the normal or in the patient with right atrial hypertrophy [2,5]

Recording of P loops in most clinical laboratories requires very careful attention to skin preparation electrode placement, respiratory phase of recording careful grounding of patient and equipment high amplification and use of one of the techniques to eliminate QRS and T data

Zoneraich and Zoneraich [88] have opened a new area for vectorcardiographic investigation with their concept of intra atrial conduction disturbances They have properly pointed out the parallel between the ventricular fascicular conducting system and the very similar internodal connections which join the SA node to the AV node and which pass through the atria They used extremely high amplification (300 mm per millivolt) and high frequency recording Using such technology to record normal P loops confirmed the location of the maximum vector as left inferior and posterior as described by other workers and also confirmed the previously observed normal rotation of the P loop as counterclockwise in the frontal and horizontal planes and clockwise in the right sagittal plane Two small notches were observed in normal patients one in the efferent and the other the afferent limb Maximum anterior or posterior voltages were confirmed as less than 0 1 millivolts Although the Zoneraichs described four different patterns for their patients with intra atrial conduction disturbances all patterns included many fine notches and bites These were frequently visible only in the vector display and not in the scalar presentations Such bites and notches were observed with and without left atrial dilatation as determined echocardiographically The Zoneraichs hypothesized that the bifid P wave scalar contour may well correspond to a lesion in the Bachmann bundle The authors comment [3] on the difficulties in assessing the separate contributions of conduction delay hypertrophy or dilatation to the observed P loop morphology

Vectorcardiographic studies of patients with atrial arrhythmias have been reported In low atrial rhythms either occurring spontaneously or pacemaker induced an expected shift of the maximum P vector occurs with a displacement to the right (left atrial rhythm) or to the left (right atrial rhythm) The rotation of the P loops in the frontal and horizontal planes varies according to the site of origin of the P loop and of the first atrium activated In the presence of inferior or low atrial rhythms no criteria are presently available for the identification of right or left atrial overload Vectorcardiography has been obtained in patients with atrial flutter [2,5,287] In 55 patients Zoneraich and co workers [83] described two vectorcardiographic patterns of flutter One, an elliptical smooth loop was found in 63% of patients with normal sized left atria and the second was a distorted flutter vectorcardiographic loop with many notches and bites This occurred in 67% of patients with enlarged left atria [3]

Following conversion of flutter patients to sinus rhythm notches and bites characteristic of intra atrial conduction delay were found in 62% of patients with enlarged left atria and in 43% of patients with normal sized atria by echocardiography Although the electrical activity in flutter is continuous masking the onset of activation correlations with prosthetic valve movement[285] seem to indicate that the onset of left atrial activation and contraction coincides with the rapid superiorly and posteriorly directed forces in the vectorcardiogram Right atrial activation then follows

Bartall and associates have studied the vectorcardiography of atrial fibrillation using timed loops Their criterion for detecting left atrial enlargement was a maximal VCG F wave exceeding 0 12 millivolts This was found in 25 of 38 subjects (66%) However only 10 of the 38 patients with atrial fibrillation had electrocardiographic F waves exceeding 0 1 millivolts in amplitude as measured in Lead V Of the 25 patients with increased F wave voltage by vectorcardiogram 21 had large left atrial dimensions by echocardiography Although the timed horizontal plane vectorcardiogram appears to be superior to Lead V of the electrocardiogram in atrial fibrillation in identifying enlargement of the left atrium additional explorations of this interesting area appear indicated

Wolff Parkinson White syndrome (references 2 to 16 290 to 303)

The vectorcardiography of QRS complexes in the W P W syndrome bears certain resemblances to the vectorcardiography of QRS complexes from ectopic ventricular sites In both types of loop the initial forces are inscribed with conduc

predicting not only the location of akinetic or dyskinetic segments after myocardial infarction but it has some value in predicting the extent of such dysfunction

11 Vectorcardiography has some of its greatest diagnostic value in patients with left bundle branch block Valuable clues to the presence of infarction in various areas as well as to right ventricular hypertrophy may be obtained

12 The vectorcardiography of pacemaker induced QRS complexes may strongly suggest the presence of underlying myocardial infarction A change in direction of the vectorial direction of the pacemaker spike itself may be a clue to wire fracture

13 High amplitude vectorcardiography of the P waves is a strong diagnostic tool in the recognition of right or left atrial overloads and is probably the best method available for the detection and evaluation of intra atrial conduction disorders

14 T loop vectorcardiography is of value in identifying unexpected rotations or speed of inscription which may frequently be a clue to ischemic disease in addition to identifying a secondary T abnormality as in bundle branch blocks

15 In children with the Wolff Parkinson White syndrome vectorcardiography provides valuable clues to the diagnosis of congenital heart disease

The author wishes to thank Mrs Esther Skolnik for invaluable help in reviewing the references and Mrs Marian Ango for her excellent secretarial work

bundle branch block Although some cases of type A pre excitation coexisting with apparent bundle branch block have been described this has never been reproduced experimentally and even the authors have no satisfactory explanation for the phenomenon Fortunately this last ... on is very rare

The diagnosis of myocardial infarction with ... Wolff Parkinson White syndrome is ... mely difficult if not impossible In one paper a patient with myocardial infarction had intermittent W P W syndrome The infarction abnormalities were totally obscured by the aberrant nature of the early forces when pre excitation was present although they were very visible with normal conduction

In one little-recognized area the recognition of congenital heart disease vectorcardiography may play a significant role in the presence of W P W Miller and Victorica have described the importance of the relationship between the delta and the main QRS axis in children suspected of congenital heart disease When these axes are more or less parallel congenital heart disease is usually absent For example a Type A pre excitation with an anterior QRS loop or a Type B with a posterior QRS loop would be more consistent with the absence of congenital heart disease However when these vectors are opposite in direction congenital heart disease was generally found Further the displacement of the major or mean QRS vector is generally oriented as expected for the appropriate ventricular hypertrophy Thus a posterior QRS vector in the presence of anterior delta vector suggests left ventricular hypertrophy In contrast right ventricular hypertrophy is more likely when the mean QRS is anterior despite a posterior delta vector in W P W Type B An interesting exception of this general rule is found in Ebstein s abnormality of the tricuspid valve Here Type B (posterior delta vector) is commonly found but the major QRS axis is also posterior In these patients the delta vector is also oriented in a superior direction

Indications for vectorcardiography

1 In the evaluation of clinically normal patients who have abnormal electrocardiograms especially apparently increased or decreased anterior forces the vectorcardiogram may be entirely normal comfirming the clinical impression

2 In the evaluation of chest pain problems with an apparently completely normal electrocardiogram a T loop study may disclose abnormal rotation of a wide but left and anterior horizontal loop This excellent sign of lateral ischemia may be completely hidden in the scalar record

3 Although high QRS voltage is better detected by scalar ECG criteria than by vector cardiographic or the orthogonal lead criteria the separation of right or left ventricular hypertrophy from combined hypertrophy is better accomplished by vectorcardiography

4 The vectorcardiogram is valuable in the differential diagnosis between pulmonary emphysema and anterior infarction

5 The vectorcardiogram is valuable in comfirming the presence of abnormally large anterior QRS forces and is particularly helpful in separating patients with right ventricular hypertrophy from patients with true dorsal infarction However it must be always remembered that anterior conduction delay Wolff Parkinson White Syndrome and hypertrophic and other cardiomyopathies may produce an identical picture Multiple myocardial infarctions are best recognized in the vectorcardiogram particularly when combined with bundle branch block or divisional block

6 The vectorcardiogram may also be of value in identifying the site of entrance of a bypass tract as free wall or septal in Wolff Parkinson White syndrome

7 Right ventricular hypertrophy is frequently easily diagnosed by vectorcardiography when it is only suspected in the conventional electrocardiogram

8 The diagnosis of right ventricular hypertrophy combined with right bundle branch block is frequently possible by vectorcardiography although care must be taken to avoid false positive diagnoses The combinations of right bundle branch block with inferior or superior divisional block are readily evident in the vectorcardiogram

9 With vectorcardiography it is possible to diagnose inferior infarction even in the presence of initial inferior forces which produce positive deflections in Leads 3 and aV_F of the scalar electrocardiogram Further it is possible to diagnose anterior infarction even in the presence of initially positive deflections in the right precordial leads

285 Alderman E L Rytand D A Crow R S Finegan R E and Harrison D C Normal and prosthetic atrioventricular valve motion in atrial flutter Correlation of

tricular premature beats ventricular tachycardia and fibrillation as well as atrioventricular conduction disturbances have been reported to occur with phenothiazine therapy[5,10,13,14]

Kelly and co workers[5] reported fatal heart block and ventricular tachycardia in two patients treated with large doses of thioridazine and Desautels and associates[14] reported a case of non fatal ventricular tachycardia In 1965 Hollister and Kosek described six cases of sudden death in the absence of cardiac disease following phenothiazine treatment In all six patients a syncopal seizure episode was immediately followed by cardiorespiratory arrest In one case resuscitation was temporarily accomplished and irreversible ventricular fibrillation was documented on the electrocardiogram These patients were all receiving drug in the acceptable therapeutic dose range[12]

Lesstma and Koenig[15] reported fatal ventricular tachycardia in a 24 year old female treated with chlorpromazine thioridazine and stelazine Unexpected death in 12 patients receiving phenothiazine drugs was reported by Moore and Book[16] No adequate anatomic explanation for death was found in these cases and the ECGs were not available Death associated with ventricular arrhythmia was reported by Giles and Modlin[17] in a 19 year old male The fatal event followed repolarization changes seen on the ECG tracing and bouts of ventricular irritability[17]

Alexander and Nino[3] described tachycardia and left bundle branch block in a 36 year old asymptomatic man who was treated with phenothiazines However this patient received concomitant tricyclic antidepressant therapy which can also cause conduction disturbances[1] Fowler and colleagues in 1975[19] described electrocardiographic changes and cardiac arrhythmias in eight patients treated with psychotropic drugs Although most patients received more than one drug thioridazine seemed to be responsible for ventricular tachycardia in five of these eight patients and one of these episodes was fatal in a 35 year old female Supraventricular tachycardia was seen in one patient on chlorpromazine

The pathogenesis of phenothiazine induced rhythm disturbances is still unknown Prolongation of the Q T U interval has been demonstrated to be associated with ventricular arrhythmias.[19,20] Prolongation of the QT interval by phenothiazines suggests an increased duration of ventricular refractoriness and a low threshold for multiple ventricular responses and ventricular fibrillation[10,21] It is known that phenothiazines have a vagolytic effect and elevate plasma catecholamine levels which also may explain its arrhythmogenic effects

Lesions in the central nervous system particularly in the brainstem can affect the ECG repolarization process[23] The effect of phenothiazine on the ECG may be related to their profound action on the brainstem It is also possible tha the microscopic intramyocardial lesions describe in some patients treated with phenothiazine might be the basis for the abnormal electrocardio grams[5,4]

Although there is a slight risk of arrhythmi with therapeutic doses of phenothiazines the drugs have well documented antiarrhythmi effects[5,27] In experimental animals thioridazin caused a significant reduction of acetylcholine induced atrial fibrillation as well as a reversion o atrial fibrillation to normal sinus rhythm[7] I addition this agent caused a long lasting suppre sor action on ventricular ectopic tachycardi produced by two stage coronary ligation Th quinidine like properties of phenothiazines co tributes to the antiarrhythmic activity of the drugs

Hemodynamic effects of phenothiazines

A powerful vasodilator action has been demon strated with chlorpromazine[8] This vasodilato effect is caused by the blockade of peripher adrenergic receptors and a direct action of th drug on the smooth muscle of the arterial wal In addition the drug has a central nervous sy tem effect which contributes to its vasodilator activity Chlorpromazine has also been shown t have a direct depressant action on the myoca dium[1]

Effects on blood pressure

As a result of the peripheral vasodilatory an negative inotropic effects of phenothiazine hypotension is the most common side effect see in patients without congestive heart failure Afte several weeks of chronic therapy patients develo tolerance to the hypotensive effects of the dru and blood pressure returns to near normal leve However in some patients a certain degree o orthostatic hypotension persists This advers effect is more commonly seen with chlorproma zine and thioridazine than with the piperazin derivatives[1]

effects of phenothiazines

Elkayam M D
ıam Frishman M D *
Orange Calif and Bronx N Y

The phenothiazines are widely used drugs in medicine today In fact there are more an two dozen phenothiazine compounds being ed in medical practice [1] Chlorpromazine (Thorazine) and other phenothiazine derivatives are employed primarily in the treatment of patients with psychoses However they are also important antiemetic agents and some phenothiazine preparations are now being used for their antihistamine and analgesic effects as well

Experimental and clinical observations have demonstrated that phenothiazines have significant electrophysiologic and hemodynamic effects which may be of clinical importance The state of knowledge regarding the cardiovascular effects of phenothiazines will be reviewed

Electrophysiology and effects on the electrocardiogram

Experimental evaluations in animals demonstrated a significant effect of phenothiazines on the action potential of isolated atrial and ventricular muscle as well as Purkinje fibers Arita and Surawicz[3] showed that phenothiazines reduced membrane responsiveness by decreasing the maximal rate of rise of phase 0 of the action potential The psychotropic drugs also cause a decrease in the amplitude of phase 2 as well as a reduction in the rate dependent change in the duration of this phase Phase 3 was found to be prolonged following phenothiazine administration The electrophysiologic properties of phenothiazines are similar to those reported for quinidine [4] This explains the similar effects of phenothiazines and quinidine on the surface electrocardiogram

In man the earliest electrocardiographic change produced by phenothiazines is lengthening of the QT interval which is accompanied by widening blunting and notching of the T wave [5] These changes reflect the disturbances in ventricular repolarization and were found by Huston and Bell[6] in 53 of 106 (50%) hospitalized psychiatric patients receiving therapeutic doses of phenothiazines This study and others suggest that the T wave changes are benign Increasing doses of phenothiazines produce lowering and inversion of the T wave the ST segments are usually not affected but may be depressed [7] These drugs can prolong the PR and QRS intervals but have no effect on the P wave Electrocardiographic changes occur most commonly after the therapeutic administration of thioridazine are less pronounced after therapeutic doses of chlorpromazine and even less common after trifluoperazine [5,8]

The degree of electrocardiographic repolarization abnormality secondary to phenothiazine ingestion appears to be dose related 200 mg per day of thioridazine can sometimes be associated with detectable ECG changes while these changes occur more consistently with doses exceeding 800 mg per day [5,9]

Arrhythmogenic activity and antiarrhythmic effects of phenothiazines

Various arrhythmias have been attributed to the effects of phenothiazine therapy The arrhythmogenic effects of phenothiazines like quinidine can occur with therapeutic doses [1] Sinus tachycardia atrial fibrillation and flutter ven

namic effects of intravenous chlorpromazine immediately after open heart surgery in 24 patients with high mean arterial pressures The average intravenous dose of 10 3 mg resulted in a significant decline in systemic blood pressure right and left atrial pressures and the pulmonary artery pressure There was no significant change in stroke volume however, cardiac output increased secondary to a significant rise in heart rate Chlorpromazine therapy caused a marked fall in both systemic and pulmonary vascular resistances

Hemodynamic effects on chlorpromazine in heart failure due to acute myocardial infarction

Significant beneficial effects on the hemodynamic profile were demonstrated by Elkayam and co workers[36] in 12 patients with acute myocardial infarction complicated by congestive heart failure The administration of 2 5 to 27 5 mg of chlorpromazine given as an intravenous bolus in increments of 2 5 mg repeated every 5 minutes was followed by a significant reduction in systemic vascular resistance and in mean capillary wedge pressure[36] (Figs 1 and 2) The drug also produced a marked elevation of cardiac output without a significant change in heart rate and mean stroke work index Although the administration of chlorpromazine resulted in a mean blood pressure fall of 18% the transmyocardial pressure gradient was not affected (Fig 2) The hemodynamic improvement was also accompanied by a dramatic increase in urine output Chlorpromazine therapy evoked a considerable degree of sedative effect and a decrement in motor activity in most of the patients

Cardiogenic shock

Dietzman and Lillehei[7] advocated phenoxybenzamine and chlorpromazine for treatment of cardiogenic shock They reported a reduction of the vasoactive response which results from an increase in circulating and tissue levels of catecholamines in patients with cardiogenic shock This vasodilatory effect of chlorpromazine mediated by the alpha adrenoceptor blockade of the pre and post capillary arteries and venules of the skin and viscera improved tissue perfusion and metabolism The authors concluded that this effect caused a decrease in morbidity in some patients

Data by Gulotta in 1970 and from Elkayam and co workers in 1977[36] also described the ber ficial effect of chlorpromazine in the low cardi output syndrome associated with open heart su gery and cardiogenic shock due to acute myoca dial infarction

Summary

Phenothiazines have significant electrophysi logic and cardiocirculatory effects The electr physiologic effect of these drugs is similar to th reported for quinidine Phenothiazines decrea the rate of rise of phase 0 of the action potenti decrease the duration and amplitude of phase and prolong phase 3 The surface ECG chan produced by phenothiazines are lengthenin the QTC interval ST T wave changes increas size of U waves and prolongation of the P interval The degree of repolarization abnormal ties secondary to phenothiazines seems to l dose related

Various arrhythmias have been attributed t the effect of phenothiazine therapy and nume ous cases of sudden death as a result of fat arrhythmia have been described Paradoxicall phenothiazines such as chlorpromazine and thio ridazine also have been shown to have significar antiarrhythmic properties Chlorpromazin shows a powerful vasodilatory effect which i caused by alpha adrenergic receptor blockade central action and a direct effect on the vascula wall In addition the drugs also have a direc depressant effect on the myocardium As a resul of peripheral vasodilatation and negative inotrop ic effects hypotension is the most commo adverse reaction of phenothiazines in patient with no evidence of congestive heart failure

Experimental studies have demonstrated si nificant reductions in systemic and pulmonary vascular resistance as well as systemic blood pressure following intravenous administration of chlorpromazine These hemodynamic changes were accompanied by significant increase in car diac output in one study and by no change in cardiac output in another study The vasodilatory effect of chlorpromazine resulted in increased renal and mesenteric blood flow and prolongation of survival time in dogs following hemorrhagic hypotension Chlorpromazine was found effective in relieving abnormal vascular tonus and improv ing the circulation in patients undergoing cardio-pulmonary bypass surgery In patients with myocardial infarction complicated by congestive

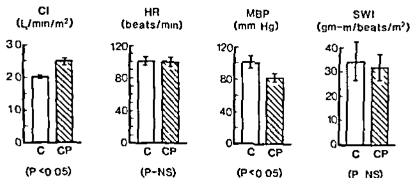

Fig 1 The effects of intravenous chlorpromazine *(CP)* vs baseline-no therapy *(C)* on cardiac index *(CI)* heart rate *(HR)* mean systemic blood pressure *(MBP)* and stroke work index *(SWI)* in 1? patients with congestive heart failure due to acute myocardial infarction The values are presented as means ± standard errors, *NS* = not significant (Reproduced by permission from Chest 72 6?3 6?7 1977)[14]

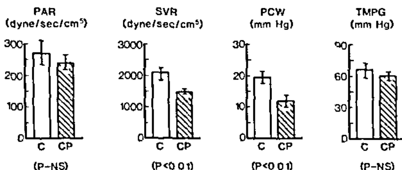

Fig 2 The mean effects of intravenous chlorpromazine *(CP)* vs baseline no therapy *(C)* on pulmonary arteriolar resistance *(PAR)* systemic vascular resistance *(SVR)* pulmonary capillary wedge pressure *(PCW)* and transmyocardial pressure gradient *(TMPG)*

Effect on systemic and pulmonary circulation

Goldberg and associates examined the effects of chlorpromazine on the pulmonary and systemic circulation in dogs The administration of an intravenous dose of 1 mg/kg produced a striking increase in cardiac output and a marked decrease in pulmonary vascular resistance The systemic vascular resistance and systemic blood pressure also fell significantly with no significant change seen in the heart rate

Similar experiments performed by Maxwell and co workers[1] demonstrated somewhat different results Using 1 mg/kg of chlorpromazine heart rate increased significantly and was accompanied by a marked reduction in systemic vascular resistance These changes were accompanied by a significant fall of systemic blood pressure and no change in cardiac output

Hemorrhagic shock

Inglis and associates have demonstrated prolongation of survival time in dogs treated with small intravenous doses of chlorpromazine following hemorrhagic hypotension Chlorpromazine increased renal blood flow and glomerular perfusion and significantly improved the renal medullary circulation[3] The beneficial effect of chlorpromazine on the renal circulation was accompanied by an improvement in cortical and medullary metabolism[33] and was associated with an increase in measurable diuresis during low levels of blood pressure The administration of chlorpromazine was also associated with a marked elevation of the mesenteric blood flow at an arterial blood pressure of 30 mm Hg

Cardiac surgery

Lemieux and colleagues[34] have demonstrated the effectiveness of chlorpromazine in relieving abnormal tonus of blood vessels in 30 patients undergoing cardiopulmonary bypass surgery The administration of the drug was associated with increased perfusion as indicated by an increase in percent oxygen saturation of venous blood and in urine output

Stinson and colleagues[35] studied the hemody

Limited pressure control to "optimum" levels *may reduce the rate of myocardial infarction* in hypertensive subjects

For more than 20 years it has been clear that *therapeutic* reduction of the blood pressure in hypertensive subjects dramatically lessens their increased liability *to illness* and death from left ventricular failure renal damage *and hemor* rhagic stroke while failing to make any incontestable *impres sion upon their similarly heightened susceptibility to myocar* dial infarction and sudden cardiac death The general reaction to this seeming paradox has been *one of pained disbelief* followed by renewed determination to squeeze *the pressure* down still further After all close relationships can be demon strated between hypertension and premature *arteriovascular* degeneration involving the blood *supply to various other* organs Why should the coronaries be different? Such reason ing makes *the unjustified assumption* that the effects of pressure change within *the arteries* supplying the brain and kidney must be the same as those *created within the nutrient* circulation of the heart It also takes no account of the extent to which high *blood pressure* should be reduced Surprisingly little attention *has been paid to* this important question and still less to another that is *even more fundamental* What is the mechanism whereby hypertension increases the infarction rate?

It has long *been thought* to do so by favoring coronary atherogene is The doctrines of pressure normalization and *of early treatment* in the young rest upon this widespread belief Yet the best that can be said for it is that the Framingham *studies have* shown a rising parallel between hypertension and the clinical manifestations of coronary *heart disease* This association has been readily accepted as *proof that* hypertension plays a significant role in the patho *genic processes within the coronary vessel walls The inference is ill founded* High blood pressure tends to precipitate angina and *myocardial* infarction in the pre ence of pre existing coronary *atheroma* whatever its origins Rather is there good reason to accept Pickering s view that hypertension is lowly *correlated* with coronary atheroma in this differing from the rest *of the arterial* irculation no doubt for the reason that the structural and *functional characteristics* of the heart are themselves unique In an angiographic assessment of risk *factors for atheroma* in 1'3 patients with and without coro nary *atheroma* the vessels being accounted as normal moderately or severely atherosclerotic Frick and his col leagues *found th t* the difference in the prevalence of *hypertension d d not* reach statistical significance in any comparison between *the groups*

In a pathological study of patients dying of congestive heart *failure Davis and* Klainer found marked coronary artery disease in 23 out of 2, *patients without hypertension* and in only 26 out of 49 patients with hypertension Later Harrison and Wood concluded that the coronary arteries vary sharply between hypertensive and ischaemic cases in the former they are large with smooth bores in the latter they are narrow frequently occluded Progression studies in coronary an raphy and experimental physiology [1] have pointed t same conclusion

There remains however a second possibility Mc *research has indicated that there may be important rela* ships between hypertension mental and physical stress, ticularly isometric stress sympathetic over activity e catecholamine circulation and potentially lethal ca arrhythmias [1, 4] This work is interesting in the context observation made by Berglund and colleagues In an ana of the rate of nonfatal myocardial infarction sustaine hypertensive patients under treatment as compared with in controls they noted that a significant benefit from pre reduction occurred early and continued throughout fo up So swift a response suggests the preemption of infar threatened by a precipitating rather than by a long factor A surge of very high pressure could be such a fa

It may be then that hypertension increases the ra infarction and sudden cardiac death largely by the occas precipitation of these events rather than by any signif influence upon coronary pathogenesis But if this be so has beta blockade with its promise of cardioprotection brought no clearly recognizable improvement? A recent s has suggested a po sible answer to this question

In a survey of middle aged severe essential hypert subjects most of them male followed under treatment o mean period of more than six years the final obse diastolic pressures (F D P s) as last recorded before moment of infarction or its avoidance in the patients who *suffered first myocardial infarction* were compared with in the patients who had avoided it There were no statist ly significant differences between the two groups in the n values for the other main coronary heart disease (C H D) factors But the relative risk of myocardial infarction sudden cardiac death in the patients with F D P reduce $<$ 90 mm Hg (Phase IV) was more than five times gre than that in the patients with F D P in the range of *100* mm Hg (P $<$ 0 01) the difference tailin off with F D about 110 to 114 mm Hg (Table I) This bimodality further illustrated by incidence comparisons between three major ranges of F D P —76 to 91 mm Hg 95 to 109 Hg and 110 to 140 mm Hg The ratios of patients infarctions to numbers *in each range* were respectively 10 of 41 4 out of 58 and 15 out of 70 Only in those whose F levels remained above 120 mm Hg did a clearly increased of infarction begin to reappear Other arteriovascular com cations were somewhat less than expected *from* patients under treatment despite relatively modest ind falls in many of them

Moreover in those who had developed an infarct

eart failure intravenous administration of ılorpromazine caused significant hemodynamic nprovement and a considerable degree of seda on The drug was found effective in reducing the asoactive response in patients with cardiogenic ıock which resulted in improved tissue perfusion nd metabolism

Exercise and recurrence of myocardial infarction

The hypothesis that vigorous exercise rehabilitation is of benefit to patients following myocardial infarction is current ly being tested in Southern Ontario using a stratified ran domized controlled trial To date 50 of the 751 patients have been followed to the point of reinfarction and the resultant data has now been analyzed seeking clues to those individuals with an above average risk of a further coronary event

The most striking feature of this survey is the similarity of patients who infarct and those who do not' While the Southern Ontario multicenter sample included some individu als who had a slow progressive extension of their disease in *many individuals the second infarction (like the first)* occurred with little clinical or physiological warning This may reflect the nature of patients referred for exercise reha bilitation all were by selection under 54 years of age while the exercise program may have attracted cases with a relati ely mild initial episode and/or a fairly complete restoration of myocardial function

The only clinical clue to the likelihood of reinfarction gained from the patient s initial records was a history of multiple infarctions. Characteristics of the initial attack (symptomatology ECG changes enzyme changes cardiac arrest dysrhythmia and minimum systolic blood pressure) did not modify subsequent prognosis Presumably residual myocardial function is more crucial than the characteristics of the previous acute episode The referral process and criteria of admission to the multicenter trial may also have sorted out a relatively uniform type of patient suited to exercise with an infarct of less than average severity
